As cationics are nonvolatile, the contribution which GC can make to their analysis is in determination of their alkyl substitution. This is achieved by a degradation reaction. Alkyltrimethylammonium and dialkyldimethylammonium cationics are converted by Hoffmann degradation to their alk-1-enes by heating on a water bath for 30 min with potassium *t*-butoxide in benzene–DMSO (4 : 1). After extraction and clean-up, the alkenes are separated on a glass column (2 m \times 3 mm i.d.) of 5% SE-30 on Chromosorb W AW-DMCS (80–100 mesh) temperature programmed from 160°C to 270°C at 6°C per minute with nitrogen as carrier gas and FID.

Alkyl chain distribution can also be obtained by thermal decomposition in the chromatograph injection port followed by separation on a 1 m \times 2 mm i.d. column packed with 8% Carbowax 20M (KOH treated) on acid-washed Chromosorb W (80–100 mesh) and programmed from 70°C to 210°C at 8°C per minute with nitrogen as carrier gas and FID.

The chain-length distribution for cationics containing ester linkages is obtained by alkaline hydrolysis followed by extraction of the resulting fatty acids and conversion of the acids to their methyl esters. (See below for separation conditions.)

Cationic surfactants are more amenable to HPLC than to GC analysis as HPLC can analyse the intact molecule. The separation of mono-, di-, and trialkyl methylammonium quaternaries uses a column 250 \times 4.6 mm of 5 μ m RSil Polyphenol with guard column, a mobile phase gradient from 90 hexane–10 THF–methanol to 10 : 90, both solvents containing 5 mmol L⁻¹ trifluoroacetic acid, and evaporative light-scattering detection.

Cationics of the structure alkylamidopropyl-*N*-(2,3-dihydroxy)-*N,N*-dimethylammonium chloride have been analysed on a column (150 \times 4 mm i.d.) of μ -Bondapak CN with water–acetonitrile–THF (57 : 42 : 1, v/v) containing 0.1% trifluoroacetic acid as mobile phase and differential refractive index detection. Quantification is with an external standard and the method has also been applied to cosmetic as well as detergent products. Cationics of the structure difatty acid ester of 2,3-dihydroxypropyltrimethylammonium chloride can be separated into mono- and di-esters on a Partisil PAC column 250 \times 4.6 mm i.d. with chloroform–methanol–acetic acid (94 : 6 : 0.1, v/v) as mobile phase and refractive index detection.

The separation of imidazoline type cationics on a column (150 \times 4.6 mm i.d.) of 3 μ m Develosil ODS-3 with 0.1 mol L⁻¹ sodium perchlorate in methanol–acetonitrile–deionized water (60 : 60 : 5, v/v) as mobile phase and UV detection at 240 nm has been demonstrated. This procedure gives separation of different chain-length alkyl substitution.

A final example of separation of dialkyldimethylammonium quaternaries on a column of 5 μ m PLRP-S with a mobile phase of 5 mmol L⁻¹ methanesulfonic acid in 70% acetonitrile uses post-column ion suppression and atmospheric pressure ionization mass spectrometry for component identification. TLC can be used to separate and compare cationics of the dialkyldimethylammonium, fatty acid esters of 2,3-dihydroxypropyltrimethylammonium, and fatty acid esters based on methyltriethanolamine quaternaries on a single plate. Separations are by numbers of substituent groups and the different structures are also separated. Conditions are Merck HPTLC Silica HF₂₅₄ with a developing solvent chloroform–methanol–acetic acid–water (72 : 20 : 5 : 3, v/v). Visualization can be with iodoplatinate spray reagent.

Soap

Soap, the sodium salt of fatty acids in the chain length range C10 to C18 (Figure 11) is analysed by protonation of the salts to their acids and derivatization of the acids with boron trifluoride–methanol to give fatty acid methyl esters. A wide range of stationary phases and conditions have been used for the separation (Figure 12). The fatty acids obtained from soap can be analysed by HPLC without derivatization using a column (150 \times 4 mm i.d.) of 5 μ m Hitachi Gel 3056 at 50°C with methanol–5 mmol L⁻¹ tetrabutylammonium phosphate (3 : 1, v/v) at pH 7.5 with conductivity detection.

Betaines

Betaines are amphoterics. The two most common types are alkylbetaines and alkylamidopropylbetaines. The alkyl moiety of the latter is generally based on coconut fatty acids.

Separation by chain length of both types of betaine is obtained on a cation-exchange column, Nucleosil 100-5 SA, 5 μ m, 250 \times 4 mm i.d., with a mobile phase of 70% acetonitrile–30% 0.05 mol L⁻¹ lithium hydroxide in water adjusted to pH 1.6 with phosphoric acid (v/v). A column temperature of 40°C is used together with diode array detection at 210 nm.

Contaminants

Common contaminants in commercial surfactants are ethylene oxide, 1,4-dioxane, sultones and dialkyltetralins.

Figure 11 Sodium salt of palmitic acid.

Figure 12 C8 to C22 fatty acid methyl esters. Column: Chrompack CPSIL5, 10 m \times 0.32 mm i.d., film 0.12 μ m, temperature programme 50°C to 200°C at 15°C per minute. Carrier helium at 1.5 mL per minute, FID, cool-on-column injection.

Ethylene oxide is used for ethoxylation of alcohols and alkylphenols. Levels of unreacted ethylene oxide are defined and must not be exceeded in the finished raw material.

Ethylene oxide in alcohol ethoxylates is determined by equilibrium headspace analysis. An aliquot of the vapour is analysed on a column (8 ft \times 0.125 in) of Chromosorb 102 (80–100 mesh) (a gas–solid phase) programmed from 120°C (5 min) to 190°C (10 min) at 8°C per minute, with helium as carrier gas and FID. A detection limit of 1 μ g g⁻¹ is achieved. An alternative column, also used for ethylene oxide in AES, is 3 m \times 1.8 mm i.d. 0.8% THEED/Carbopack C (80–100 mesh).

For improved quantification, both methods can be adapted to a method of standard additions.

1,4-Dioxane is a by-product of the sulfation of alcohol ethoxylates. The industry standard method is equilibrium headspace GC and involves sample preparation using the method of standard additions for quantification. There is some flexibility as to whether capillary or packed columns are used and the actual phase required.

An alternative approach describes the use of a totally deuterated 1,4-dioxane analogue with isotope dilution and MS detection to minimize matrix effects. The separation is carried out on a 60 m \times 0.32 mm i.d. column of Supelcowax 10, temperature programmed from 50°C (2 min) to 100°C at 5°C per minute.

An HPLC approach for 1,4-dioxane in alkylether sulfates is a column (250 \times 4.6 mm i.d.) of 5 μ m LiChrospher C-8 with an aqueous acetonitrile gradient and UV detection at 200 nm. An external calibration curve is used for quantification.

1,3- and other sultones occur as by-products of the formation of α -olefin sulfonates. Certain sultones are potent sensitizers and must be controlled. 1,3-Sultones are determined in α -olefin sulfonates by extraction with diethyl ether, trapping from a silica column, and GC on a column (1 m \times 3 mm) of 2% DEGS on Chromosorb W AW-DMCS (60–80 mesh) at 220°C with helium as carrier and flame photometric (sulfur mode) detection.

Alternatively, detection limits down to 0.2 ng g⁻¹ can be obtained with negative chemical ionization MS with methane as reagent gas. 1,3-Sultones can also be determined by HPLC following extraction from α -olefin sulfonate and separation on a column (200 \times 4.6 mm i.d.) of 5 μ m CPS Hypersil with hexane–ethyl acetate (90 : 10, v/v) as mobile phase and differential refractive index detection. Quantification is by external standard.

Dialkyltetralins occur in linear alkyl benzene, the precursor of LAS. Again, there are set limits as to permissible levels. They are determined on a column (250 \times 4 mm i.d.) of 5 μ m Lichrosorb Si60 with dry iso-octane as mobile phase and UV detection at 254 nm. A reference standard is available from ECO-SOL to calibrate the method.

Future Developments

As has been described above, there are many alternative approaches to the chromatographic analysis of commercial surfactants. The approach to be used for any analysis may be determined by a number of factors, the information required, the equipment available, the time available to carry out the analysis. As we move into the twenty-first century, there will be a trend towards faster analysis and analysis requiring less sample handling. Automation will increase, requiring less and less skilful human input. Data handling will become faster and more intelligent in order to deal with greater volumes of data generated in shorter times. Use of new separation techniques will be investigated, particularly electro-driven techniques and some will replace existing techniques for certain analyses. Overall, separation systems will become smaller with advantages of lower solvent and carrier gas use, less use of laboratory space, and with

increased portability to permit use away from the laboratory.

Introduction

Liquid chromatography (LC) is very useful for the characterization of individual surfactants. Most commercial surfactants are mixtures of members of homologous series, and LC is capable of defining these mixtures according to their homologue distribution, indicating, for example, alkyl chain length or degree of polymerization. LC is also the preferred technique for the quantitative determination of many surfactants, especially ionic surfactants in mixtures. The utility of LC stems from the properties of surfactants – these compounds have good solubility in the usual LC mobile phases and possess diverse chemical functionality, but at the same time they are not volatile enough for ready analysis by alternative technologies such as gas chromatography (GC) or simple mass spectrometry (MS). The structures of common surfactants are given in **Table 1**.

Surfactants are usually analysed in LC systems containing a substantial percentage of organic solvent so as to inhibit micelle formation. The presence of micelles will confound LC analysis.

Formulations and Mixtures of Surfactants

LC is used for quality control of formulations such as cleaning compounds and pharmaceutical prepara-

tions. LC is often the easiest and most specific method for determining surfactant concentration in a well-understood mixture. On the other hand, LC is not often useful for analysis of unknown formulations unless MS detection is available. This is because of the limited separation range of any single LC system.

Sometimes, especially in quality control where there are no unknown components, no preliminary sample work-up is necessary. This is particularly true of ionic surfactants. More often, especially for non-ionics, a gross separation of the surfactants from the matrix is required. This can be accomplished by solvent extraction of the dried solids or by liquid-liquid extraction or solid-phase extraction (SPE) of an aqueous solution.

Alkylarylsulfonates and alkylphenol ethoxylates can be determined with a minimum of sample work-up because of the availability of a specific detection method, fluorescence, to distinguish them from other surfactant and nonsurfactant compounds that may also be present. For the very common mixtures of anionic and nonionic surfactants, ion exchange chromatography systems result in nonionic surfactants eluting prior to anionics, while reversed-phase systems result in the nonionics being retained longer than anionics.

Environmental Analysis

LC is widely applied in environmental analysis, but it is not used for routine monitoring of effluents, except by industry for the analysis of specific process streams

Table 1 Structures of common surfactants

Surfactant	Structure
<i>Cationic surfactants</i>	
Quaternary amines	$RR'R''N^+Cl^-$ $R, R', R'', R''' = H \text{ or } C_1-C_{18} \text{ alkyl or } C_6H_5CH_2$
<i>Anionic surfactants</i>	
Linear alkylbenzene sulfonates	$4-RC_6H_4SO_3^-Na^+$ $R = C_{10}H_{21}-C_{14}H_{29}$
Alkyl sulfates	$ROSO_3^-Na^+$ $R = C_8H_{17}-C_{18}H_{37}$
Alkanesulfonates	$RSO_3^-Na^+$ $R = C_8H_{17}-C_{18}H_{37}$
Ether sulfates	$4-RC_6H_4O(CH_2CH_2O)_xSO_3^-Na^+$ or $R'O(CH_2CH_2O)_xSO_3^-Na^+$ $R = C_9H_{19}; R' = C_{12}H_{25}-C_{18}H_{37}; x = 2-10$
α -Olefin sulfonates (mixtures of alkenesulfonates and hydroxyalkanesulfonates)	$RSO_3^-Na^+$ $R = C_{11}H_{21}-C_{20}H_{39} \text{ or } C_{11}H_{22}OH-C_{18}H_{36}OH$
Ether carboxylates	$RO(CH_2CH_2O)_xCH_2COO^-Na^+$ $R = C_{12}H_{25}-C_{18}H_{37}; x = 5-25$
Sulfosuccinate esters	$ROOCHSO_3CH_2COOR^-Na^+$ or $HOOCCHSO_3CH_2COOR^-Na^+$ $R = C_8H_{17}$
α -Sulfofatty acid methyl esters	$RCH(SO_3^-)COOCH_3Na^+$ and $RCH(SO_3^-)COO^-2Na^+$ $R = C_{12}H_{25}-C_{16}H_{33}$
<i>Nonionic surfactants</i>	
Alkylphenol ethoxylates	$4-RC_6H_4O(CH_2CH_2O)_xH$ $R = C_8H_{17}, C_9H_{19} \text{ or } C_{12}H_{25}; x = 3-50$
Alcohol ethoxylates	$RO(CH_2CH_2O)_xH$ $R = C_{12}H_{25}-C_{18}H_{37}; x = 5-60$
Acid ethoxylates	$RCOO(CH_2CH_2O)_xH$ $R = C_{11}H_{23}-C_{17}H_{35}; x = 5-20$
EO/PO copolymers	$HO(CH_2CH_2O)_y(CH(CH_3)CH_2O)_x(CH_2CH_2O)_yH$ $x = 16-70; y = 1-100$
Esters	$\begin{array}{c} \text{O} \\ \parallel \\ \text{CH}_2\text{CHOHCHOORCHCH}_2\text{OHCH}_2\text{OOR} \end{array}$ $R = C_{16}/C_{18} \text{ alkyl}$

where the composition is uniform and well understood. The standard wastewater methods, for example those based on colorimetric tests, give a gross value for total surfactant concentration and are most suitable for routine environmental monitoring.

LC is used, however, in special investigations of environmental impact to give information on the concentration and degradability of specific surfactants in particular environmental areas, relying on the ability of LC methods to precisely characterize surfactant homologues. A preliminary separation or preconcentration is always necessary. The most common pretreatment method nowadays is SPE, especially when low levels of surfactant must be determined. C_{18} media are most often applied, in the form of SPE cartridges or extraction discs. Nonpolar resin of the poly(styrene/divinylbenzene) type is also used. A secondary separation of the surfactants into nonionic, cationic and anionic fractions can be performed on ion exchange media.

LC is the method of choice for determining anionic surfactants in the environment. It is also preferred for the determination of the anionic degradation products of these surfactants. LC is the best method for the determination of nonionics (especially when coupled with MS), if detail on homologue distribution is needed. LC is less often applied to environmental determination of cationics, since interference is not as serious a problem with the standard methods for determining cationics in wastewater as it is for other surfactants.

Analysis of Individual Surfactants

Anionic Surfactants

LC analysis of anionic surfactants is a mature technology. Detection is a simple matter, either by direct UV absorption of aromatic surfactants or by inverse photometric detection of the aliphatic compounds.

Alkylarylsulfonates The commercial product, linear alkylbenzenesulfonate (LAS) is a mixture containing a range of alkyl chain lengths, typically C_{10} – C_{14} . Reversed-phase LC with a C_4 or C_8 column effectively separates LAS according to the length of the alkyl chain (Figure 1). A C_{18} packing gives a more complex chromatogram because the individual compounds of discrete alkyl chain length are themselves partially resolved into isomers; in many cases this resolution is not needed or desired (Figure 2). In any case, GC analysis after desulfonation is a better method for determining isomers. Aqueous mixtures of acetonitrile, methanol and tetrahydrofuran (THF) are appropriate mobile phases, generally containing a salt such as 0.1 mol L^{-1} sodium perchlorate. Detection is by UV absorbance at 225 nm or fluorescence with excitation at 225 nm and emission at 290 nm. Fluorescence detection is advantageous for trace analysis.

Alkyl sulfates Alkyl sulfates with chain lengths in the surfactant range (C_{10} and higher) are readily separated according to increasing alkyl chain length in a reversed-phase system with methanol/water mobile phase containing a salt such as sodium perchlorate. The pH is often adjusted to 2.5 or 3.0. Gradient programming is impractical if detection is by direct low wavelength UV, differential refractive index (DRI) or conductivity. Gradients are successful with detection by indirect UV (typically, methylpyridinium chloride is added to the eluent) or evaporative light scattering (ELS). If anion exchange chromatography is used, elution is in order of decreasing alkyl chain length.

Alkanesulfonates These are generally separated with the same systems used for alkyl sulfates. In a mixture, the peaks of the alkyl sulfates and alkanesulfonates are interspersed, with the alkyl sulfates more strongly retained on reversed-phase column packings than alkanesulfonates of the same chain length. Separation from anionic surfactants of other types is usually straightforward. Interference from alkyl sulfates can be eliminated by subjecting the sample to acid hydrolysis to convert them to the corresponding alcohols and sulfuric acid; sulfonates are not affected by this treatment.

Ether sulfates Alkylphenol ether sulfates and alcohol ether sulfates can be resolved by reversed-phase chromatography with elution in the order of both increasing alkyl chain length and increasing (or decreasing) ethoxy chain length (Figure 3). An alkylamine ion-pairing agent may be added to increase retention time. Unsulfated alcohol or alkylphenol ethoxylate impurities elute first under paired-ion con-

Figure 1 LAS isolated from river water and analysed isocratically using a C_4 reversed-phase column. Labels indicate alkyl chain length. Column: Wakosil 5C4, $4.6 \times 150 \text{ mm}$. Mobile phase: 0.1 mol L^{-1} sodium perchlorate in 50 : 50 $\text{CH}_3\text{CN}/\text{H}_2\text{O}$. Detection: UV, 220 nm. Copyright (1991) Elsevier Science.)

ditions. A single peak for easy quantification can sometimes be obtained by using a very short reversed-phase column and a step gradient.

Normal-phase systems are also used for analysis of ether sulfates, with stationary phases of bare silica or

Figure 2 Chromatogram of commercial LAS mixture analysed using a reversed-phase column and gradient elution. Labels indicate groups of isomers for various alkyl chain lengths. Column: Zorbax ODS, $4.6 \times 250 \text{ mm}$. Mobile phase: $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ gradient with increasing concentration of NaCl. Detection: UV, 225 nm. amino- or cyanopropyl-silica. In this case, the nonionic material elutes first, followed by the anionic material, each in order of increasing ethoxylation. An ion-pairing agent such as cetyltrimethylammonium chloride may be added to give more rapid elution of anionic material. A relatively hydrophilic mobile phase is often used in conjunction with the ion-pairing agent.

α-Olefin sulfonates These compounds give complex chromatograms that reflect the complexity of their composition. The commercial product is formed of approximately equal portions of alkenesulfonates and hydroxyalkane sulfonates, each carrying the chain length distribution of the alkene feedstock. Disulfonates may also be present. α-Olefin sulfonates are analysed by reversed-phase LC with methanol/water and added salt. DRI or low wavelength UV detection is suitable. Elution is in order of increasing chain length, with hydroxyalkanesulfonates eluting prior to the corresponding alkenesulfonates and with all disulfonates eluting prior to all monosulfonates (Figure 4). Complete resolution is not obtained if the starting α-olefin was a mixture of many chain lengths, as is usually the case with commercial products.

Petroleum sulfonates and alkylnaphthalenesulfonates These are frequently separated on anion exchange packings with elution according to increasing degree of sulfonation. Reversed-phase systems have also been used. Resolution by alkyl chain length is

sometimes attained, but, more often, the practitioners are content with a single peak for the active agent.

Ether carboxylates Only reversed-phase systems have been demonstrated for separation of these products, generally with acetonitrile/water mobile phase. Elution is always according to increasing chain length of the alkyl or alkylphenol moiety. Depending on the system, there may be an overtone of separation according to increasing or decreasing ethoxy chain length. As with ether sulfates, separation from nonionic impurities is straightforward. Alkylphenolether carboxylates are easily detected in the UV (225 or 254 nm), while the alkylether carboxylates require low wavelength UV, DRI or ELS detection.

Sulfosuccinate esters These are analysed most readily by reversed-phase LC in the presence of an ion-pairing agent. If not monodisperse as to alkyl chain length, they are eluted in order of increasing alkyl length. Separation from other anionic surfactants can usually also be accomplished by reversed-phase chromatography.

α-Sulfofatty acid methyl esters These also are easily separated according to alkyl chain length by reversed-phase methods. Ion-pairing agents are rarely used.

Soap Fatty acids are separated according to increasing alkyl chain length on a C₁₈ column with methanol/water mobile phase and refractive index

Figure 4 Chromatogram of α-olefin sulfonate after hydrogenation and formation of methyl esters. Peak identification: 4- and 3-hydroxyhexadecylsulfonate, methyl ester; 4- and 3-hydroxyoctadecylsulfonate, methyl ester; hexadecylsulfonate, methyl ester; octadecylsulfonate, methyl ester. Column: Inertsil C₁₈, 4.6 × 250 mm. Mobile phase: MeOH/H₂O, 85 : 15. Detection: refractive index. (Reproduced with permission from Matsutani S and Endo Y (1991) Separation and determination of sulfonate type anionic surfactants including 2-sulfonatofatty acid methyl ester by methyl ester derivatization and HPLC analysis. *Yukagaku* 40: 566–573.)

detection. Ionic strength and pH must be controlled. Analysis is either at low pH without an ion-pairing agent or at high pH with ion-pairing. It should be noted that most practitioners prefer GC for analysis of fatty acids (as methyl esters).

Cationic Surfactants

LC is the most generally useful method for determination of cationic surfactants. All commercial cationic surfactants are salts of quaternary amines (quats). Most of these, like the long-chain alkyltrimethylammonium salts, have good water solubility and are readily analysed by reversed-phase LC. Control of pH and ionic strength is necessary and inverse spectrophotometric detection gives the best results for quats without an aryl moiety; toluenesulfonate or xylenesulfonate are used as counterions for detection. Retention times are influenced by the hydrophobicity of the counterion. Conductivity detection is also applicable, especially if ion chromatography instrumentation is used with a nonpolar stationary phase (this configuration is sometimes called 'mobile-phase ion chromatography'). Of course, UV detection can be used for compounds with pyridyl or benzyl substituents. Since quats exhibit long retention times on C_{18} stationary phases, reversed-phase LC is most often performed on cyano columns, usually with methanol/water or acetonitrile/water mobile phase.

Quats are sometimes analysed using cation exchange packings. While the separating ability of the ion exchange systems is not as great as that attained with normal- or reversed-phase systems, ion exchange is sometimes preferred for formulation analysis because interference is minimized in that only the cationic materials are seen.

The quats used as fabric softeners for household laundry contain two long alkyl chains and have poor water solubility. For reasons of solubility, these are most easily analysed by normal-phase chromatography. Bare silica stationary phases are never used, but rather cyanoamino, amino, DIOL or polyphenol phases. Chloroform/methanol mobile phases work well, usually with a little added acetic acid. Conductivity and ELS are suitable for detection.

Common fabric softener quats, including ester quats, can be characterized by normal-phase chromatography on a polyphenol column with a hexane/methanol/THF gradient and added trifluoroacetic acid. Elution is in order of decreasing alkyl length, with the quats well resolved from unquaternized amine impurities.

For trace analysis, detection is sometimes accomplished by paired-ion extraction of the HPLC effluent with a fluorescent anion, followed by phase separation and fluorescence detection.

Nonionic Surfactants

Ethoxylated nonionics are most easily characterized by normal-phase chromatography. This permits the separation of the compounds according to the length of the ethoxy chain, with the longer chain homologues eluting later. Amino-bonded stationary phases are often used along with the usual nonpolar mobile phases such as hexane.

Separation of homologues can also be accomplished by reversed-phase chromatography. Reversed-phase LC is usually applied to higher ethoxylates because normal-phase LC resolution deteriorates with higher molecular weight. Solvent systems of methanol/water or acetonitrile/water are usual. Order of elution can be according to increasing or decreasing order of ethoxylation, depending on the particular reversed-phase media and solvents used, the particular nonionic surfactant and whether it has been derivatized. The order of elution even depends on the molecular weight: elution is sometimes according to reverse order of ethoxylation for lower members of a series and according to increasing order of ethoxylation for higher members of the same series.

Reversed-phase HPLC is effective for separation of ethoxylated surfactants according to the identity or chain length of the hydrophobic moiety. Caution is required, since under various reversed-phase conditions separation according to degree of ethoxylation will also occur, as mentioned above. Unless MS detection is available, this two-dimensional separation makes quantification difficult, so the system is usually optimized to minimize the influence of hydrophilic homogeneity. If MS detection is used, then the separation by hydrophobe is sufficient for complete characterization of the surfactant, with the MS detector giving the information on ethoxy homologue distribution. The sensitivity of the MS detector is not identical for all homologues. For precise work, calibration must be performed over the entire range of composition.

Size exclusion chromatography (SEC) is sometimes applied to the analysis of nonionic surfactants, particularly higher molecular weight surfactants like the ethylene oxide/propylene oxide (EO/PO) copolymers. Nonaqueous systems are most useful for this analysis for two reasons. First, formation of micelles is discouraged. Micelle formation is a function of concentration, so SEC can show different values for molecular weight depending on sample concentration. Second, aqueous SEC column packings often have a silica backbone. Polyethoxy compounds are strongly adsorbed to silica, resulting in mixed-mode separation rather than separation only according to molecular size.

Polyethylene glycol (PEG) impurity is determined in most ethoxylated surfactants by reversed-phase separation with 95 : 5 methanol/water and DRI or ELS detection. PEG elutes as a single peak prior to the surfactants.

The refractive index of nonionic surfactants is a function of degree of ethoxylation. Thus, the response of a differential refractive index detector varies for homologues, with the variation being most significant at low degrees of ethoxylation.

Alcohol ethoxylates (AE) Commercial products are mixtures of homologues containing a distribution of alkyl chain length and ethoxy chain length. Conventional LC analysis fails to give a single peak for alcohol ethoxylate. Rather it yields a series of peaks more-or-less resolved corresponding to the alkyl or ethoxy distribution. This limitation is only overcome by using backflush techniques.

Derivatives may be formed to improve detectability of AE. Derivatization also influences retention time, so that a gradient system optimized for underivatized AE must be modified for chromatography of the derivatives. Typical derivatizing agents are phenyl isocyanate, naphthyl isocyanate and 3,5-dinitrobenzoyl chloride. Fluorescence detection is sometimes used in environmental analysis with fluorescent derivatizing agents such as 1- and 2-naphthoyl chloride and naphthyl isocyanate.

Normal-phase chromatography, preferably on aminopropyl- or cyanopropyl-bonded silica, will give the ethoxy distribution (Figure 5). Reversed-phase chromatography on C_{18} media serves to separate by alkyl chain length. In either case, solvent programming is usually required for complete resolution of a commercial product, so either an ELS detector is used or the surfactant is first derivatized to permit use of a UV detector. If reversed-phase solvents are not optimized, a separation by ethoxy chain length is superimposed on the separation by alkyl chain length.

Alkylphenol ethoxylates (APE) Almost all commercial products are based upon a monodisperse hydrophobe, usually nonylphenol. Therefore, quantification is usually performed by reversed-phase chromatography on C_{18} media using an isocratic methanol/water or acetonitrile/water eluent and UV detection, resulting in a single peak. Octylphenol ethoxylates are easily separated from nonylphenol ethoxylates by such systems.

As with alcohol ethoxylates, separation by degree of ethoxylation is easily performed with any of the usual normal-phase stationary phases, with the cyano packings most popular. Amino and bare silica media are also used (Figure 6). Reversed-phase LC is also applied, especially for higher degrees of ethoxylation.

Figure 5 Chromatogram of C_{13} alcohol ethoxylate from a biotreatment study. Analysis using a CN normal phase column with gradient programming and evaporative light scattering detection. Labels indicate ethoxy chain length. Column: Rainin Microsorb CN, 4.6×250 mm, 45°C . Mobile phase: gradient, hexane/THF/(90 : 10 2-PrOH/ H_2O); from 100 : 0 : 0 to 80 : 20 : 0 in 5 min, then to 52 : 30 : 18 in 15 min, then to 40 : 40 : 20 in 5 min. Detection: ELS (Reproduced with permission from Dubey ST, Kravetz L and Salanitro JP (1995) Analysis of nonionic surfactants in bench-scale biotreater samples. *Journal of the American Oil Chemists' Society* 72: 23–30.)

UV detection (225 or 275 nm) is always used since it gives a uniform molar response to the homologues. For trace analysis, fluorescence detection is applicable since APEs have native fluorescence.

Ethoxylated acids These compounds can be considered as esters of PEG and fatty acids, with the commercial products also containing diester, residual fatty acid and free PEG. Reversed-phase chromatography with methanol/water separates the ethoxylated acid, PEG diester, free PEG and free fatty acid, and usually also serves to separate the compounds from other surfactants. As with other ethoxylates, normal-phase chromatography gives resolution by ethoxy chain length. SEC is often useful to resolve the

Figure 6 Chromatogram of a mixture of two commercial products, nominal 4-mole and 30-mole ethoxylates of nonylphenol, analysed by normal-phase HPLC. Column: Hewlett-Packard Si-100, 4.6×200 mm, 30°C . Mobile phase: gradient; A = 80/20 *n*-hexane/ethyl ether; B = 40:30:20:10:1:0.5 dioxane/ethyl ether/*n*-hexane/2-PrOH/ H_2O /HOAc; 5 to 95% B in 45 min. Detection: UV, 280 nm. mono- and diesters. DRI and ELS detectors are most applicable. Low wavelength UV detection must be used with caution because of the disproportionate response from unsaturated fatty acid moieties.

Esters Esters of fatty acids with glycerol and sugars are separated according to degree of acyl character by either normal-phase or reversed-phase chromatography. Reversed-phase elution is according to increasing acyl character, while normal-phase elution is in order of decreasing acyl character (i.e. according to both the chain length of the acyl groups and their number). Normal-phase LC is usually performed with a DIOL stationary phase and propanol/water mobile phases. The ELS detector is most applicable, although historically many applications have been developed using DRI or UV at wavelengths of 220 nm or less.

EO/PO block copolymers In the absence of interfering compounds, polymers of the poloxamer type can sometimes be determined by reversed-phase HPLC with methanol, but the most common separation technique is SEC. The copolymers useful for detergents and pharmaceuticals are higher in molecular weight than most other synthetic surfactants, so SEC can be used for both qualitative and quantitative

analysis. If conventional LC is used, depending on the specific product, a reversed-phase system with acetonitrile/water can be optimized to be indifferent to EO chain length, separating the surfactant according to length of the PO chain. DRI detection is generally used for the block copolymers.

Alkanolamides These compounds, for example the C_{10} – C_{18} fatty acid monoethanolamides, are eluted according to increasing acyl chain length by reversed-phase chromatography with methanol/water solvents. These systems may also be used for formulation analysis. Detection is a challenge: DRI and low wavelength UV are most common, and ELS and nitrogen-specific detectors have been applied in more recent times. *N*-Methylglucosamides are analysed in the same way.

Alkyl polyglycosides Reversed-phase LC with methanol/water will separate these compounds, with elution according to increasing chain length of the acyl constituents. For compounds of the same acyl chain length, polyglycosides elute prior to monoglycosides. ELS detection is typically used.

Amphoteric Surfactants

Amphoteric surfactants are almost always separated on C_{18} columns with methanol/water mobile phase. The pH is often held as low as the column will tolerate and a salt such as sodium perchlorate is added. Under such conditions, the amphoteric surfactant behaves much like a cationic surfactant and the same detection methods are used as discussed above for cationics.

Betaines These compounds can be separated, with elution by increasing alkyl chain length by reversed-phase LC or by decreasing chain length using cation exchange chromatography. DRI detection is most often chosen, although low wavelength UV and ELS are sometimes applied.

Phosphatides These compounds must be discussed separately from other amphoteric. They are constituents of the natural surfactant, lecithin, but they also have great biochemical importance. Normal-phase LC serves to separate the main constituents of commercial lecithin: phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, phosphatidylserine and phosphatidic acid. (Each of these consists of a number of individual compounds containing various acyl groups.) The normal-phase separation is traditionally performed on a bare silica column with low wavelength UV detection. Since it is mainly double

bonds that give the detector response, and since each of the individual components contains acyl chains of varying unsaturation, quantification by UV is only approximate. The ELS detector is rapidly becoming standard for this analysis. Since this detector is tolerant of solvent gradients, other normal-phase columns, notably the DIOL column, may be used instead of bare silica. These give better reproducibility but do not have sufficient resolving power for lecithin analysis in the absence of gradient programming.

Separation by acyl chain length is accomplished by reversed-phase LC of fractions separated by the normal-phase methods. LC-MS is an obvious way to simplify the characterization of unknowns. Precise phosphatide analysis is very much an activity of specialists and the field is advancing rapidly.

Conclusions

LC is the only practical method to characterize many surfactants according to their oligomer or homologue distribution. It is also the best way to determine quantitatively many surfactants, particularly ionic surfactants.

However, in spite of improvements in instrumentation and in stationary phases, LC is not easy. It demands more time and training of the operator than most analytical techniques. Preliminary sample preparation is very often necessary for mixtures and environmental samples, making an LC analysis an expensive analysis.

Continued development in the areas of detection (especially in element-selective detectors, detectors specific for chemical functionality, and LC-MS interfaces) will make LC even more useful in the future. For example, the ELS detector, even though suffering from problems in linearity in its present incarnation, has already greatly expanded the utility of LC for analysis of lecithin and ethoxylates.

SYNTHETIC POLYMERS

Gas Chromatography

J. K. Haken, The University of New South Wales, Sydney, NSW, Australia

Copyright © 2000 Academic Press

Introduction

Successful gas chromatography (GC) requires that the sample be volatile at the operating temperature. The majority of synthetic polymers are of substantial molecular weight, i.e. in excess of 20 kDa, and not amenable to direct chromatographic examination.

Figure 1 shows the molecular weight limitations of compounds suitable for gas and liquid chromatography. Monomers with molecular weights in the range 50–100 Da are particularly suitable for direct GC.

Performance-enhancing or compounding additives in polymers are also usually amenable to direct examination. The major difficulty with these materials is separation or extraction from the polymer matrix, which generally accounts for over 90% of the product. Plasticizers form a major part of many polymer compounds and monomeric plasticizers may frequently be examined directly or after extraction. Polymeric plasticizers, and polymeric additives after separation, require examination by pyrolysis or by spectrometric tools. The finely divided polymer is subjected to thermal desorption or extraction or digestion with solvents. Extraction with supercritical fluids is finding greater use and has the advantage that the removal of extraction solvent is simplified.

To increase the volatility of polymers, a reduction in molecular weight must be achieved. This is most commonly carried out by pyrolysis or thermal degradation in the absence of oxygen, or to a lesser extent by chemical degradation, which is applicable to most condensation polymers. Both techniques are indirect methods of analysis where the polymer is characterized by analysis of the volatile products of the degradation. A recently developed technique, known as pyrolytic methylation, effectively combines both methods and is applicable to condensation polymers. To date this new technique has found its major application in forensic science.

Pyrolysis

Pyrolysis techniques possess several advantages. The sample preparation is negligible, while the time for

analysis is relatively short in comparison with that needed for other instrumental techniques. In addition the sample required for pyrolysis is small.

Pyrolysis was originally carried out separate from the GC instrument, but *in situ* pyrolysis in a device directly attached to the GC was soon universally employed. The pyrolysers available are of two basic types:

- (1) Furnace type. The polymer sample is introduced into a heated microfurnace attached to the injection port of the chromatograph and the volatile pyrolysis products are rapidly swept into the column by the carrier gas.
- (2) Pulse mode type. The polymer is attached to the pyrolysis element, which is rapidly heated to a predetermined temperature. The volatile pyrolysis products are rapidly swept into the chromatograph as before. The pyrolysis element may be either a filament or ribbon device that is resistively heated or a Curie point device. With Curie point heating the polymer is deposited on a wire of ferromagnetic material. The wire is rapidly heated to its Curie point using induction. A range of wires with Curie points from 358°C for a nickel wire to 980°C for a wire consisting of 50 : 50 iron and cobalt are available. Ribbon and filament pyrolysers normally use materials of high resistance that are inert in nature, such as platinum or other noble metals; this reduces the possibility of reactions occurring with the degraded sample.

Both types of pyrolysers are used, each type having both advantages and disadvantages, but the two pulse mode instruments are most widely utilized.

The first application of pyrolysis and gas chromatography was in 1954, when vinyl polymers

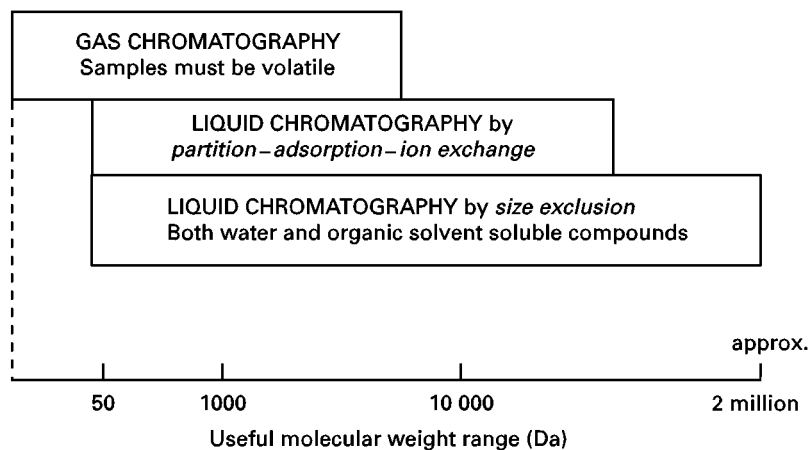

Figure 1 Approximate useful ranges of common chromatographic procedures. (Reproduced from Haken JK (1990) *Trends in Analytical Chemistry* 8:14 with permission of Elsevier Science Publishers.)

and copolymers were heated at 650°C in a stream of nitrogen. The volatile products were condensed and subjected to gas chromatography. *In situ* pyrolysis quickly followed with the use of a filament device, which was little different to that which has subsequently found extensive usage with almost every conceivable type of polymer.

Early workers used large samples, which resulted in poor heat transfer, the occurrence of combination reactions of the volatile fragments and the production of nonreproducible results. Bibliographies of papers and compilations of pyrolysis results, both as pyrograms and bar charts, date from the 1960s, but the early literature is of limited value as the reproducibility is often poor, and the techniques used do not always represent current practice. Libraries of pyrograms have appeared in texts, but the experimental conditions are frequently omitted and it is difficult to reproduce the results.

It has long been recognized that small samples, typically much less than 1 mg, good heat transfer, rapid heating of the pyrolysis element and rapid removal of the degradation products from the heated zone are essential in achieving reproducible results.

Packed chromatographic columns were widely used in the early work, but capillary columns that offer enhanced separation are now almost universally employed. The detection limits of the flame ionization detector, the mass spectrometer and the Fourier transform infrared detectors in current use are orders of magnitude better than that required by the smallest possible pyrolysis sample. In the 1980s a sample of 800 ng of acrylic polymer would produce a mass spectrum of about 30 compounds when pyrolysed. More recently samples of 1 µg have been used for forensic casework, while sample sizes of 2 µg have been generally used, the major difficulty being in handling and weighing these small samples. With such quantities a chromatogram containing dozens of peaks can be obtained and a mass spectrometer attached to the GC will provide a mass spectrum of each peak. The spectra may be interpreted offline or in many cases may be identified by simultaneous online matching with an inbuilt computer containing a library of spectra, which shows the degree of probability of the match.

Pyrolysis Temperature and Heating Time

The temperatures used for pyrolysis are variable and depend to some extent on the nature of the polymer. Polymers of high thermal stability or which are highly crosslinked obviously require a higher temperature than a simple thermoplastic. The bond strengths of the constituent atoms and the association of atoms influence both the ease and type of degradation that

occurs, as rupture of the weakest bonds will predominate. The formation of stable free radicals generally occurs. Little pyrolysis of polymers occurs with the lowest available Curie point wire, i.e. 358°C and temperatures of 500–600°C might be considered as lower limits. The optimum temperature is considered to be near 800°C. An excessively high pyrolysis temperature is to be avoided, as with increasing temperature fragmentation of the pyrolysis products occurs, with an increased amount of very low molecular weight gaseous products being formed. These products are not helpful in achieving identification as they are typical of organic compounds generally rather than of a particular polymer.

The heating time, while variable, is short and may range from seconds to a fraction of a second. With Curie point pyrolysis the heating period is usually less than with filament or ribbon types. In either case the time to achieve the final temperature must be short. Pyrolysis under the conditions selected must be essentially complete, a situation that is readily checked by reheating the element after pyrolysis and determining if further pyrolysis products are separated. The flow rate of the carrier gas that passes through the pyrolyser should be such that the pyrolysis products are readily swept from the heated pyrolysis zone into the column, minimizing the recombination of reaction products. Such secondary products may be more characteristic of the apparatus than of the polymer. The unreactive carrier gases normally used can be conveniently employed. Gases that react with the reaction products are used in special circumstances, the most common being oxygen for use in oxidation studies or hydrogen with a suitable catalyst for hydrogenation.

An advantage of the resistively heated pyrolyser is that stepwise pyrolysis, where the same sample is pyrolysed at increasing temperatures, may be carried out. This technique has been used with low temperatures to remove the majority of additives and monomeric plasticizers, and also with higher temperatures to study the ease of polymer degradation. A disadvantage of resistively heated pyrolysers is that the resistance of the heating element may vary over time owing to corrosion and thinning of the wire. With a variation in the resistance of the wire, the nominal temperature is not achieved when the same current is applied and the pyrolysis results are variable.

Enclosed Curie point pyrolysis (ECP) has been described where the sample is deposited on the Curie point element and sealed in a capillary tube, with pyrolysis taking place in the tube. The tube is subsequently broken in the carrier gas flow. The method has been used for the study of the oxidation of polyisobutylene. A comparison with conventional resistive pyrolysis and ECP shows that a method for

distinguishing gas phase versus melt phase secondary reaction is possible.

Polymer Degradation

Degradation may occur by a variety of mechanisms, or combination of these. The common mechanisms are described below.

Most addition polymers incorporate a carbon-carbon backbone. With a polyolefin such as polyethylene, the bonds are equivalent and the rupture is random. The strength of the C-C bond is approximately 349 kJ mol^{-1} (83 kcal mol^{-1}) and that of the C-H bond is approximately 393 kJ mol^{-1} (94 kcal mol^{-1}), so that rupture of the former bond occurs. In these circumstances a large number of fragments result and the mechanism is termed random scission. The hydrocarbons with terminal free radical ends require to be stabilized. The fragment with a free radical end may extract a hydrogen atom from an adjacent fragment and become a saturated end. In extraction a free radical is created on the adjacent fragment. This fragment commonly stabilizes by β -scission, where the induced free radical site becomes an unsaturated molecule end. This process continues and produces a sequence of three hydrocarbons, the first saturated, the next with a double bond at one end, and the third with a double bond at both ends, a series of n -alkanes, α -olefins and α,ω -diolefins being formed from methane to hydrocarbons of near 40 carbon atoms.

Where the carbon atoms are not equivalent, such as in polyvinyl chloride where the bond strength of the C-Cl bond is 305 kJ mol^{-1} (73 kcal mol^{-1}), random scission does not occur – rather aromatic compounds are formed. Hydrogen chloride is eliminated and the free radicals on the adjacent sites form a sequence of double bonds to make an unsaturated backbone. This then fragments to form a series of aromatic compounds.

A third mechanism that occurs with a few polymers containing α -methyl substitution, i.e. polymethyl methacrylate and polymethyl methacrylamide, is unzipping or reformation of monomer. Here fragmentation of the C-C backbone occurs with the free radical fragments formed undergoing β -scission with the elimination of a molecule of monomer and formation of a new free radical fragment. Repeated β -scission leads to the formation of more monomer, which is frequently in excess of 95% of the original monomer concentration. The yields of monomer vary greatly with the polymer. The lower polyalkyl methacrylates yield essentially all monomer, but as the substituent alkyl chain becomes larger the monomer yield decreases. With polylauryl methacrylate the monomer yield is approximately 70%, as some degradation of the alkyl chain occurs.

Polystyrene degrades by a combination of mechanisms, and the monomer yield is approximately 40%. Unzipping reactions are of little importance in the degradation of polyacrylates, where the monomer yield is in the order of 5%.

Microstructure

Pyrolysis GC of polymers allows determination of the microstructure in addition to the chemical composition. The polymer of simplest chemical composition, polyethylene, is prepared by polymerization under different conditions and with a variety of catalysts to produce products with greatly differing physical properties, dependent on the microstructure. Short- and long-chain branching occurs, as does stereoregularity.

First to be analysed were polymers produced by high pressure processes. These contain a significantly branched structure with both short-chain branching (C1-C6) and long-chain branching, as illustrated in Figure 2A. The introduction of low pressure processes using metal alkyl catalysts has allowed the production of products with structures as shown in Figure 2B and 2C.

The low density polymer produced by high pressure processes undergoes random scission and produces a strong sequence of triplet peaks corresponding to α,ω -diolefins, α -olefins and n -alkanes of each carbon number, with weak multiple peaks of isoalkanes, isoalkenes and isoalkadienes between the triplets.

A technique that has been used in polyolefin pyrolysis for decades is *in situ* simultaneous hydrogenation of the pyrolysis products, hydrogen being used as the carrier gas with a pre-column containing

Figure 2 Structures of various polyethylenes. (A) Low density polyethylene (LDPE); (B) high density polyethylene (HDPE); (C) linear low density polyethylene (LLDPE). (Reproduced from Wampler TP (1995) *Applied Pyrolysis Handbook*, p. 81 with permission of Marcel Dekker.)

a hydrogenation catalyst inserted between the pyrolyser and the injection port. With this technique the triplets become single peaks of the *n*-alkane and the intermediate peaks are reduced in number and increased in intensity, with iso compounds of comparable structure forming single isoalkane peaks.

While ethylene is symmetric, propylene and other olefins are not, and the possibility of head to tail, head to head and tail to tail combinations exists; such differences are evident in pyrograms. With copolymers of polyethylene and polypropylene, pyrograms containing peaks associated with each monomer are observed; however, with different catalysts the intensity of the individual peaks vary. This is used as a measure of the sequence distribution of monomer units along the chain. Sequence distribution determination is not restricted to polyolefins, but has also been reported with many other important polymer systems.

The tacticity of various polymers, including polystyrene, has been determined by pyrolysis gas chromatography. With polystyrene, fragments characteristic of the polystyrene chain, ranging from monomer to pentamer, were observed in the pyrogram. The relative intensities of the tetramer and pentamer peaks reflect the original tacticity.

Minor and subtle differences in the end groups of a particular polymer system frequently cause significant alterations of the properties of the polymer, particularly concerning thermal stability and transparency. It is well known in gas chromatography that the polysiloxane materials frequently used as stationary phases possess high thermal stability when appropriate end termination is employed. Details of end termination are also of value in determining polymerization mechanisms. The identification and determination of end groups is difficult owing to their low concentration. Pyrolysis-GC has been used to characterize many polymer systems. Examples are polymethyl methacrylate radically polymerized in toluene solution with benzoyl peroxide initiation under varying conditions. The peak intensities of some products characteristic of the end groups present have been interpreted in terms of polymerization temperature and solvent/monomer in the feed.

Methacrylate end groups in polystyrene samples have been determined by reaction with tetramethylammonium hydroxide where methyl methacrylate was split out and determined. The initiator used was *s*- or *n*-butyl lithium and on pyrolysis the main product was styrene monomer together with a considerable amount of dimers and trimers. Various minor fragments clearly showed the presence of *n*-butyl end groups. Similar analyses of end groups in other polymers have been reported, including end groups in polycarbonates.

Chemical Degradation

Alkyd resin constituents have been determined for decades, the method used being chemical cleavage followed by estimation by gravimetry, colorimetric or spectrophotometric means. The analysis of alkyd resins was revolutionized in the 1960s by US Government workers who determined the reaction products by GC.

The Zeisel reaction has also been extended by the use of GC; traditionally all alkoxy groups were estimated as methoxy groups. With GC, the alkoxy groups are converted to the corresponding alkyl halides by reaction with hydriodic acid in phenol prior to chromatographic separation of the individual halides.

Gas chromatography was early applied to the estimation of the hydrolysis products of polyurethanes, polyethers, polysiloxanes and polyamides.

In situ Chemical Degradation

The degradative analysis of many polymers with *in situ* GC was developed by scientists working on determination of the volatile degradation products in the 1970s. They conducted vigorous hydrolytic cleavage in a reactor constructed from a furnace pyrolyser attached to the injection port of a gas chromatograph. A 30 mol% excess of a prefused mixture of potassium hydroxide (85% KOH approximating to the hemihydrate) and 1–10% sodium acetate as flux was heated for 0.5–1.0 h at temperatures within the range 200–350°C. Volatile reaction products were examined by GC while the reaction products that formed alkanoate soaps remained in the reactor.

All the alkali metal hydroxides have been used for alkali fusion, although potassium hydroxide is preferred as its melting point is suitable and organic compounds have greater solubility in a potassium hydroxide melt than in a sodium hydroxide melt. **Table 1** shows the melting points of the common alkali metal hydroxides in both the anhydrous and hydrated forms.

Most acids, both organic and inorganic, have been used to effect hydrolysis and to achieve cleavage of ethers. They include phosphoric, hydrochloric, sulfuric, hydrobromic, hydroiodic and *p*-toluenesulfonic acids. Mixed anhydrides of *p*-toluenesulfonic and acetic acid or trifluoroacetic anhydride or trifluoroacetic acids have also been used. Some of the acids, particularly sulfuric acid and hydrochloric acid, produce by-products, while phosphoric and hydrobromic acids have often been used successfully. The ether groups in alkylene oxide polymers have been cleaved using a mixed anhydride of *p*-toluenesulfonic acid and acetic anhydride. The reaction is

usually conducted by heating in a microflask with an appropriate condenser. The polymer may be converted to compounds suitable for GC or the reaction products may be worked up as derivatives.

External Chemical Degradation

The work described above has been extended, by employing external fusion, to allow all of the reaction products to be identified as volatile products or as derivatives amenable to GC. Hydrolytic reactions using alkaline or acidic catalysts are achieved, as is acidic cleavage of ether groups. In several cases polymers have been examined using simultaneous hydrolysis and alkylation.

The advantages of external fusion are listed below:

1. Fusion is more rapid, efficient and more readily controlled than *in situ* degradation as the water necessary for the reaction remains in the reaction environment rather than tending to be swept into the cold trap.
2. Multiple fusions can be carried out in an external heater without restricting the use of a gas chromatograph, or, more importantly, restricting examination to GC alone.
3. Materials that would ordinarily be retained in the reactor as soaps or other material of low volatility can be examined after appropriate chemical reaction and/or derivatization.
4. Hydrolytic degradation and cleavage of ether groups can be conducted simultaneously or separately.
5. Other analytical techniques can be used as appropriate.
6. All of the components of a polymer can be analysed rather than simply those sufficiently volatile for direct GC.

The quantitative nature of both acid and alkaline fusion reactions has been reported and a number of polymers have been studied with acceptable results.

Table 1 Melting points of alkali metal hydroxides

Alkali metal hydroxide	Melting point	
	Anhydrous	Hydrate
Potassium hydroxide	360	125 ^a
Sodium hydroxide	318	64.3 ^b
Lithium hydroxide	417	— ^{b,c}

^aCommercial potassium hydroxide contains 15% water and is present as the hemihydrate.

^bPresent as the monohydrate.

^cDecomposes to form lithium hydroxide and water.

Nitrogenous polymers Nitrogenous polymers have been widely studied. These include: polyamides such as the simple nylon materials; the condensation products of dicarboxylic acids and diamines and the condensation products of α,ω -aminoalkanoic acids; the dimer polyamids (using the C₃₆ dimer dicarboxylic acids prepared from vegetable oils); the aramid fibres (using an aromatic diamine and a dicarboxylic aromatic acid); and the polyhydrazides produced using hydrazine. Polyimides produced by the polymerization of benzene tetracarboxylic acids and aromatic diamines and copolymers of amides and imides have also been analysed using alkali fusion.

Polyesters External chemical degradation has been used to analyse polyesters, both containing oils and oil-free, as well as silicone alkyds and crosslinked systems of polyesters with various aminoplasts. In a crosslinked system the aminoplast butylated ureaformaldehyde is itself cleaved, while with other aminoplasts only the butylated groups are removed.

Simple fibreglass-reinforced plastic (FRP) and vinyl ester laminates are cleaved by this method. With the laminates and silicone polyesters, the siliceous fibreglass (normally E-glass, a very low alkali borosilicate glass containing approximately 50% silica and 10% boron trioxide) or organic silicone is converted into an organic derivative amenable to GC examination. A chromatogram showing the trimethylsilyl (TMS) derivatives of the polyols, dicarboxylic acids and organic siloxane moiety produced from a silicone polyester is shown in **Figure 3**. Other reinforcement materials that are used in aerospace and other specialized applications include polyester or polyamide (NomexTM) reinforcements, both of which are amenable to hydrolytic cleavage.

Polyurethanes Polyurethanes are conventionally the reaction products of an isocyanate with an ether or ester and terminated with hydroxyl groups. While these materials are relatively resistant to hydrolysis, they can be readily cleaved by vigorous hydrolytic reactions. The polyurethane ether materials are more resistant to simple solution hydrolysis than are the polyurethane esters. Many polyurethane compounds have been studied using both alkaline and acidic hydrolysis. The simple condensation products – chain-extended materials produced using a short-chain polyol or an amine; polyether polyurethanes used in medicine; transparent polyurethanes that use polycaprolactone diols; isocyanate-based copolyamide resins; and a urethane crosslinking agent used in reversion-sensitive natural rubber – have all been examined using vigorous hydrolysis reactions. Determination of the tertiary amino groups allows the

Figure 3 Gas chromatogram showing simultaneous separation polyols, dicarboxylic acids and silicate TMS derivatives of: 1, solvent peak; 2, neopentyl glycol; 3, silicate; 4, trimethylol ethane; 5, trimethylol propane; 6, adipic acid; 7, isophthalic acid. (Reproduced from Haken JK *et al.* (1985) *Journal of Chromatography* 441: 207–212 with permission of Elsevier Science Publishers.)

number of secondary amino groups in polyurethanes to be determined, and an estimate of the degree of crosslinking to be made.

Epoxy resins Only simple epoxy systems, either as the ether or crosslinked with amine compounds, can be cleaved by fusion. The majority of epoxy systems are complex networks that are sterically hindered and resistant to cleavage.

Polysulfones The aliphatic polysulfones are readily cleaved by vigorous hydrolysis. However, the aromatic polysulfones that find application as high temperature polymers, either alone or frequently as copolymers with polyethers, are resistant to hydrolytic cleavage.

Liquid crystal polyesters Liquid crystal polyesters based on *p*-hydroxybenzoic acid, *p,p*-biphenol, terephthalic acid and 2-hydroxy-6-naphthoic acid, which are also used as high temperature polymers, are readily cleaved by vigorous hydrolysis.

Summary

Systems that have been successfully subjected to chemical cleavage include polyacrylates, polyamides,

polyimides, polyurethanes, polysiloxanes, polyurethanes, polyesters (containing vegetable oil and vegetable oil-free), liquid crystal polyesters, polyhydrazides and silicone polyesters. **Table 2** shows polymers and additives that have been examined using both *in situ* and external pyrolysis. Copolymers that include more than one functional class have been examined; these include polycarbonate–polydimethylsiloxane block copolymers and isocyanate-based copolyamides.

With a completely unknown sample alkali fusion is recommended, followed if necessary by acid reaction. This ensures that some reactants, such as polyethers, are not cleaved into such small fragments that their initial composition is not apparent. For some purposes acid reaction is more rapid. For routine purposes some of the extraction steps, which simply serve to separate functional classes, may be eliminated. The reduction or elimination of extraction steps increases the quantitative nature of the analyses. It has been shown that the cleavage reactions are essentially quantitative and that errors are introduced by the extraction steps.

Pyrolytic Methylation

The term pyrolytic methylation was first used in 1979 to describe the coinjection of tetramethylammonium hydroxide with free carboxylic acids and phenols into the injection port of a gas chromatograph, resulting in the formation of methyl derivatives. The application to polymers did not occur until a decade later. Simultaneous pyrolysis and alkylation was conducted by the use of tetramethylammonium hydroxide or tetrabutylammonium hydroxide mixed with the polymer in a pyrolyser. Typically a 5 µg sample of polymer and 2 µL of the derivatizing reagent is subjected to Curie point pyrolysis at 770°C. Separation is by capillary GC with confirmation using mass spectrometric detection.

The reaction mechanism has been discussed and the evidence suggests that reactions occur by the following mechanism. When intimately mixed with tetramethylammonium hydroxide and heated to temperatures above 400°C, the polymer undergoes hydrolysis with the strongly basic agent forming salts of the hydrolysed products. These then undergo thermal fragmentation to the methyl derivatives. The term SPM, or simultaneous pyrolysis methylation, has been acknowledged to be something of a misnomer and the process has been renamed ‘thermally assisted hydrolysis and methylation’, with the abbreviation THM.

Applications

Alkyd and polyester resins The use of THM has largely been directed towards polymers that find

Table 2 Polymers and additives examined using *in situ* and external pyrolysis

Material	Product/s of reaction	Unidentified products
<i>In situ</i> pyrolysis		
Nylons	Diamine	Alkali metal soap of acid

application in surface coatings. Pyrolysis and methylation of alkyd resins gives methyl esters of the constituent acids and methyl ethers of the polyols. A soyabean oil-pentaerythritol-orthophthalic alkyd resin produced C₈-C₁₆ methyl alkylanoates from the vegetable oil; tri- and tetramethyl ethers of pentaerythritol, dimethyl orthophthalate and methyl benzoate from the benzoic acid used as the chain regulator; and cyclopentanone from scission of C-O bonds of adipic acid, dimethyl isophthalate and methyl benzoate.

The fibre polyester, polyethylene terephthalate, gave benzene, a degradation product obtained on pyrolysis, dimethyl terephthalate and methyl benzoate as a combination product. It was evident in the analysis that no product attributable to the ethylene portion of the polymer was reported. This result is different from that obtained by hydrolytic degradation and chromatography, where a component peak attributable to the ethylene or butylene chains was identified.

The partial structure of alkyd resins may be elucidated; in addition to identification of the carboxylic acids and polyhydric alcohols as the appropriate

esters and ethers, the drying oil type, degree of cure, the oil length and modification with rosin and epoxy resins may be determined. The most common polyhydric alcohols used in alkyd resins are glycerol and pentaerythritol, resulting in the formation of the di- and trimethyl esters and the tri- and tetramethyl esters, respectively. All three of the isomeric phthalic acids are readily separated on the low polarity capillary column used. Methyl benzoate is observed, which is a problem as some of this compound is due to decarboxylation of some of the phthalic acid and differentiation of the use of benzoic acid as a chain terminator is not possible. All types of oils, both vegetable and the more highly unsaturated marine types, are readily characterized before autoxidative polymerization. However, after 'drying' or autoxidative polymerization, little unsaturation remains. The relative proportion of unsaturated to saturated fatty acid methyl esters gives an indication of the cure or age of the alkyd resin. A simple alkyd resin based on linseed oil-pentaerythritol-orthophthalic acid was examined over 5 months. The following conclusions were made:

1. Before autoxidative polymerization the ratio of linolenic acid (9,12,15-octadecatrienoic acid) to palmitic acid (hexadecanoic acid) was significant but the unsaturation rapidly decreased such that after 2 days all the linolenic acid had been removed by crosslinking.
2. After 2 weeks the ratio of oleic acid (9-octadecadienoic acid) to stearic acid (octadecanoic acid) slowly began to reduce with time. After 4 months the concentration of oleic acid had been reduced by approximately two-thirds of its initial concentration.
3. Nonanedioic acid began to appear after 3 days and increased to a maximum in 1 month. The oil length of an alkyd resin is the percentage of fatty acid acylglycerols present in the total resin solids. By considering the ratio of products from the drying oil to the aromatic compounds from the phthalic acids, an approximation of the oil length may be obtained. Some decarboxylation occurs however, and the value of the estimate is reduced. Naturally occurring modifiers, i.e. rosin (as methyl dehydroabietate), have been determined, as have epoxy resins.

Epoxy resins A simple epoxy ether, i.e. a bisphenol A epichlorohydrin condensate, on pyrolysis produced three component peaks – phenol, isopropenyl phenol and bisphenol A. However, on pyrolytic methylation a variety of components was produced including phenol, isopropenyl phenol, the monomethyl ethers of these compounds and bisphenol A. The diether of bisphenol A was also formed.

Polyvinyl acetate Pyrolysis butylation has been used with low molecular weight products such as vinyl acetate-containing polymers where the vinyl acetate formed by pyrolysis is advantageously examined as vinyl butyrate, the disadvantage being that by-products, i.e. *n*-butanol and tributylamine, are formed.

Polymethyl acrylates Pyrolytic butylation of a methacrylic copolymer produced *n*-butyl methacrylate. *n*-Butyl acetate and *n*-butyl butyrate were produced from a cellulosic acetate-butyrate copolymer and *n*-butyl cyanoacrylate was produced from a commercial cyanoacrylate adhesive.

Rosin adducts The rosin-based resins have been extensively studied. While these are natural polymers, they are used in many modified forms. Abietic acid is the principal acid and it contains both a conjugated diene and a carboxylic acid, both of which are readily reacted on a commercial scale. Wood rosins contain a high proportion of diterpentine and mixtures of

seven organic acids. Pyrolytic methylation has allowed the identification of (1) fumaric acid, (2) sandaraco-fumaric acid, (3) pallstic acid, (4) isofumaric acid, (5) dehydroabietic acid, (6) abietic acid and (7) neoabietic acid.

Para-substituted alkylphenol resins or modifications with rosin or its esters produce characteristic pyrograms when subjected to pyrolytic methylation. Tertiary butylphenol and *p*-nonylphenol are the tonnage phenols used. Traces of the free phenols result from both phenol modifications and methyl- and dimethyl-substituted phenols. Pentaerythritol rosin esters produce peaks due to the methyl esters of dehydroabietic acid and abietic acid in addition to the tri- and tetramethyl ethers of pentaerythritol. Modification of rosin with fumaric or maleic acids produce dimethyl fumarate. Rosin and reaction products with fumaric acid have been detected as a size on paper at the 1% level.

Polycarbonates Polycarbonates have been cleaved using alkaline reaction. Various phenolic compounds are formed by C–C bond cleavage as well as by cleavage of carbonate linkages. Almost quantitative degradation of the main chain occurs through reactive pyrolysis at the carbonate linkages to yield the dimethyl derivatives of the constituents.

Liquid crystal polyesters As in chemical degradation, reaction occurs with liquid crystalline polyesters, partial reaction occurring with products based on *p*-hydroxybenzoic acid and 2-hydroxy, 6-naphthoic acid. Quantitative results were achieved by varying the reaction conditions. Similar liquid crystalline polyesters based on 4-hydroxybenzoic acid, terephthalic acid and 4,4-biphenol produced almost quantitative results.

Conclusion

The application of GC to synthetic polymers has been outlined using three types of methods – pyrolysis, chemical degradation and pyrolytic alkylation. In all cases a considerable reduction in molecular weight is achieved before GC. Pyrolysis is applicable to both addition and condensation polymers and occurs by thermal degradation of the constituent chemical bonds. Chemical degradation and pyrolytic alkylation are applicable to condensation polymers with degradation at the location of constituent functional groups. Pyrolysis in some cases produces quantitative results, while chemical degradation usually produces quantitative results. Pyrolytic alkylation has to date been used only for qualitative analysis.

Introduction

The goals in the use of liquid chromatography for the separation of polymers and polymer oligomers include the determination of purity, the production of pure/purer polymer mixtures and for obtaining quality control data for polymer intermediates. There are fundamentally two partition mechanism options for such separations: size exclusion or sorption in the sense of surface adsorption or dissolution into a stationary phase. Size exclusion involves the partition of the molecules of interest from the mobile phase into the stationary mobile phase contained in the various pores of the solid support. The extent to which the stationary liquid is explored by the polymer molecules is determined by their Stokes' radius (dynamic size) and the volume of mobile phase in pores of a diameter large enough for penetration to be possible. Adsorption onto or sorption into a phase coated or grafted as a thin film on the surface of a solid support is dominated by solubility in the mobile phase and the chemical potential for sorption of the polymer molecules in a given mobile phase in contact with a given stationary phase. Because stationary phase supports used in modern liquid chromatography are themselves porous, mixtures of size exclusion in the presence of sorption and *vice versa* are known.

Size Exclusion

Historically, size exclusion has been the method most often used for polymer separation, purification and molecular weight determinations. The technique developed in parallel in the 'organic' polymer area and the biological polymer area. When used in organic polymer work, the term 'gel permeation' is used. In water soluble biopolymer work, it is called 'gel filtration'. There is no fundamental difference in the principles involved and both are size exclusion based. In liquid chromatography molecules move in the direction of development because of mobile phase flow. Most gel electrophoresis methods are, in reality, size exclusion based separations and that includes the gel methods used for sequencing of nucleotide fragments. There the driving force is electromigration of molecules with essentially identical ionic mobility which reptate through a porous polymer medium at rates proportional to size.

Sorption

Despite the potential attractiveness of a method which could introduce chemical selectivity in to the separation of polymers, sorption methods have seen little practical application until more recent times. The sole exception is the ion exchange purification of polyelectrolytes such as proteins. The history of the development of polymer high-performance liquid chromatography (HPLC) is an interesting one and is detailed in subsequent paragraphs. The reader should keep the following introduction in mind when

considering various models for retention of polymers in sorption techniques.

The liquid chromatography of small molecules is dominated by solubility of the molecule[s] of interest in the moving or mobile phase. This is in stark contrast to gas chromatography where the stationary phase contribution dominates. One controls retention and the large fraction of selectivity (differential migration) in liquid chromatography by mixing various solvents to obtain differential solubility sufficient for the task of separation. That is not to suggest that the stationary phase is not important. It is, but generally as a secondary effect.

The rate of change of retention volume (or time at constant flow) for small molecules (m.w. < 2 kD) is not steep compared to polymers. Thus the strategy for small molecule separations is to use combinations of solvents in which one solvent is a good solvent and the other is more hostile or 'poorer' in terms of solubility of the molecules of interest. Polymers, on the other hand can have very rapid transitions from soluble to insoluble over narrow ranges of good/poor solvent mole fraction.

It is also common practice to inject samples of small molecules in a solvent which is good compared to the mobile phase. This technique can have awkward effects in polymer chromatography. If the mobile phase is one in which the solubility is already very small or near zero, the injected plug of good solvent moves with the leading and trailing edge of the plug being depleted of solute. The net effect is to coat the column with polymer with the excess eluting at the void volume. Columns are well-designed packed beds and, as such, are very poor mixers. The solution is to dissolve the polymer in the mobile phase and to mix the sample solution with the mobile phase before column contact.

There has been much interest in methods for the fractionation of macromolecules using reversed-phase, high-performance liquid chromatography (RPLC). Reversed-phase methods are those that have a relatively polar mobile phase and relatively non-polar stationary phase, e.g. water and paraffin oil. If it were possible to achieve both isocratic and gradient elution of polymer oligomers and isomers, then these separation techniques could provide vastly more insight and control than is currently the case in a majority of the applications where size exclusion alone dominates.

Certainly debates over the validity of models are an important scholarly aspect of the current dialogue. Successful models based on sound physico-chemical principles could guide the development of practical applications. The short-term solution is likely to be a combination of models if the historical case for the application of HPLC to small molecules applies here.

Although there are many reported successful examples of polymer separations and several models have been suggested, the retention mechanism of polymers in RPLC remains unclear. Glöckner suggests a 'precipitation-redissolution' model for the gradient elution of polymers. In this model, polymer molecules repeatedly precipitate onto the stationary phase and redissolve into the mobile phase until finally eluting at a mobile phase composition at which the polymer is totally soluble. Retention depends solely on the mobile phase with the column playing a passive role providing only a large surface area as support for the precipitate. Armstrong, Martire, Boehm and Bui proposed a model for critical solvent composition behaviour found by some in the isocratic elution of polymers. This model is often called BMAB theory or critical solution theory. This theory was developed from a statistical treatment of the equilibrium distribution of infinitely dilute polymer molecules between a mobile phase and a stationary phase based on the Flory-Huggins theory. According to the model, the range of the mobile phase composition within which finite retention factor (k) values can be observed under isocratic elution conditions is very narrow for high molecular weight polymers. Plots of $\log k$ versus the mobile phase composition show slopes that mean that polymer molecules are either infinitely retained or not retained at all. Therefore, isocratic retention should be impossible. It can be concluded from this model that the separation is strictly mobile-phase controlled and has little to do with the column length. If either of these models are correct in every detail, isocratic elution is impossible because, under isocratic elution, the polymer molecules either flow through the column without any retention or strongly adhere to the stationary phase without ever eluting.

In contrast, Snyder and coworkers assert that no special model is needed for the polymer retention and the traditional models can be used in interpreting the retention behaviour of polymers.

After numerous failures in attempts to reproduce the published work of others, Lochmüller and McGranaghan were the first to consider the likely fate of the injected polymer sample in the mobile phase prior to its contact with the column. They found that traditional retention behaviour was obtained only when the sample was adequately mixed with the mobile phase using a low dispersion, crocheted capillary tube placed between the sampling device and the column. They reported that polystyrenes of molecular weight ranging from 2000–2 800 000 Da could be separated under isocratic elution conditions with binary mobile phases of tetrahydrofuran/H₂O and dichloromethane/acetonitrile. Finite, non-zero k values

and linear relationships of $\log k$ versus the volume percentage of tetrahydrofuran and dichloromethane were observed. Alhedai, Boehm and Matire subsequently reported the isocratic elution behaviour of polystyrene homopolymers.

In polymer RPLC, separations are achieved by using a mixture of 'good' and 'poor' solvents as the mobile phase. A good solvent is one that is thermodynamically favourable for polymer solution and a poor solvent is thermodynamically unfavourable. Since polymers have low solubility in poor solvents, polymer samples are often dissolved in a good solvent for chromatography. The result is that the injected sample plug is a better solvent than the actual mobile phase. For hydrophobic polymers, the good solvent usually is a strong solvent in RPLC. Often sample preparation is followed by injection without any further treatment of the sample. Because chromatographic columns are, by their very design, poor mixing devices and the equilibration between the polymer sample and the mobile phase may be slow on the chromatographic time scale, the polymer sample can remain well solvated from its interior in the injection solvent and isolated from the mobile phase and stationary phase effects. Under the worst conditions, the mobile phase can be so hostile to the polymer that the polymer sample will co-elute with the injected plug of the good solvent. This 'solvent effect' could explain why normal chromatographic retention behaviour was not observed in some of the previous studies. In addition, polymer molecules can undergo various conformational changes in the chromatographic process due to the difference between the injection solvent and the mobile phase. These conformational changes can complicate separations and make reproducible, meaningful results difficult to obtain. The use of a pre-column mixer and an initial binary solvent whose composition is close to the mobile phase composition affords equilibration between the polymer and the mobile phase and also affords a more uniform elution condition.

There are, of course, significant differences in the properties that distinguish different polymer types from each other that must be taken into account in guiding method development. In the special case of some biological polymers such as proteins and polypeptides, a contribution of size exclusion and ion exchange is possible and careful manipulation of the ion exchange effect can provide resolution of genetically different isoenzymes. In other cases where the polymer has groups with little acid-base difference, as in the case in gene sequencing, it is possible to cleave the macromolecule at specific sequence events and to tag these fragments. The resulting fragments are then separated through size exclusion in a gel

matrix using electrokinetic driving force through the gel space. Current applications of HPLC are more limited and most of the literature examples of protein resolution are carried out with molecules differing by thousands of Daltons and are limited to 'analytical' purposes through the use of denaturing conditions where narrow peak shape is more important than retention of native structure.

Many, if not most, common organic polymers are either non-electrolytes or strong polyelectrolytes. In the latter case, the most common situation is one in which the ionized or ionizable function is the same for each repeating unit and/or the groups have nearly identical pK_a values. Ion exchange is, thus of little use in the resolution of oligomers. In the case of non-ionizable polymers, such as the polystyrenes, the methacrylates, acrylates, polyesters and ethers, the use of RPLC offers the possibility of selectivity by both solvent effect and stationary phase interaction. If ordinary chromatography is possible, then it could be possible to resolve oligomers, to resolve copolymer variations by chemical selectivity and thus improve the quantitation as well as the isolation of such materials.

There are two solutions to the steep gradient in $d \ln k / d \text{Vol}\%$. The first is to find a second at a solvent less hostile to the polymer under investigation. The second is provided by modern instrumentation and that is that a gradient mixer will mix mixtures. This second option involves running a gradient where the A solvent or poor solvent is already a mixture and the same for B. In principle, a gradient can be run from 60% A to 58% A in a way reproducible to 1% by volume A in B. In this manner, the steep gradient in $d \ln k / d \text{Vol}\%$ is slowly traversed in the gradient mixing process. The results can be dramatic and it is possible to resolve individual polystyrene oligomers at an average molecular weight of 100 kD.

Figure 1 shows a separation of two polymethylmethacrylate samples, one a synthetic sample containing lower molecular weight oligomers after gel permeation separation, and the other a nominally monodisperse 75 kD standard. Figure 2 is the linear dependence of retention as a function of tetrahydrofuran vol% in water for a wide range of polyethylene glycol monodisperse standards. Note how the slope steepens with increasing molecular weight. Figure 3 is a similar plot for poly-L-, poly-D- and poly-D,L-tryptophans. Note the linearity of response but also that the lines for all poly-L and the poly-D,L are not parallel despite the molecular weight being the same (~ 5.5 kD).

There are many good reasons to want to use a single component, isocratic elution method. The first is the cost per sample run. The second is that

Figure 1 Separation of a mixture of PMMA 33.5-kD (2) and PMMA 75-kD (3) in gradient mode with mobile phase THF/water from 68/32 to 80/20 in 20 min on a Hypersil® 20 cm \times 2 mm C18 column. only one solvent need be removed from the collected polymer sample. The potential of modern liquid chromatography is to produce samples which are truly monodisperse. The fewer separation solvents the better. A possible route is the use of a single solvent and the temperature dependence of k . Of course, the magnitude of the temperature effect on retention is in direct proportion to the solubility dependence. The temperature gradient can be applied as it is in gas chromatography, i.e. as a gradient over

time. Another is a gradient over space, the column length. The first example of a spatial gradient was in the separation of polyethylene glycols. These polyethers have a decreasing solubility in water with increasing temperature. Thus a column kept at high temperature will show large retention volumes for polyethylene glycols and a gradient run from hot to cold is an option. A column kept relatively hot at the inlet and cold at the outlet will show a reduced rate of development for polyethylene glycols at the

Thin-Layer (Planar) Chromatography

L. S. Litvinova, Institute of Macromolecular Compounds of Russian Academy of Sciences, Petersburg, Russia

Copyright © 2000 Academic Press

The use of thin-layer chromatography (TLC) in polymer analysis was first mentioned in 1968. Belenkii and Inagaki with their co-workers described separations according to the composition of random styrene-methyl methacrylate and styrene-methyl acrylate copolymers with molecular weights varying from 40 to 200 kDa. Since then polymer TLC has been developed intensively and other researchers have also begun to work actively in this field.

The mechanisms of polymer TLC have been investigated and the methods for the determination of molecular weight (MW) and molecular weight distribution (MWD) of homopolymers, such as polystyrene (PS), poly(ethylene oxide) (PEO) and poly(methyl methacrylate) (PMMA), have been developed. Impressive results were obtained for separations in accordance with different features of the polymer architecture. This investigation of structural heterogeneity of styrene-methyl methacrylate (S-MMA) copolymers have made it possible to separate random, block and alternating copolymers as well as two- and three-block copolymers. The stereoregular heterogeneity of PMMA and polybutadiene (PB) has also been determined. Styrene (S) and butadiene (BD) block copolymers have been studied and deuterated and hydrogenous PS separated.

In the vast majority of studies silica gel has been employed as a sorbent with the occasional use of

alumina. In 1976 Belenkii and co-workers reported that critical conditions exist on passing from size-exclusion to adsorption chromatography of polymers. The first reviews on polymer TLC appeared in 1977. In 1980 Glöckner demonstrated the importance of gradient elution for polymer separations, and in 1982 Armstrong and co-workers used reversed-phase plates to separate homopolymers according to MW. More recent reviews have been by Glöckner (1987) with the most comprehensive review presented by Gankina and Belenkii in 1991.

Here the behaviour of macromolecules and small molecules are compared and the mechanism of chromatographic processes and the analysis of different types of polymer heterogeneity considered.

Behaviour of Macromolecules under TLC Conditions

TLC is one of the most efficient methods used for the fractionation of polymers and the analysis of their heterogeneity. The chromatographic behaviour of polymers differs from that of low MW compounds in many ways that can be revealed even in the analysis of narrow-dispersity homopolymers. Unlike low MW compounds, polymers are characterized by physical heterogeneity, i.e. they are a mixture of macromolecules with different degrees of polymerization (polymer homologues). The concept of 'molecular weight' is replaced by the expression 'average MW', which is a statistical average value. In addition to physical heterogeneity characterized by molecular weight distribution (MWD), chromatographic

methods of analysis also enable the determination of chemical, functional, structural, stereoregular and topological polymer heterogeneity.

Macromolecules are characterized by low diffusion coefficients in solution and by even lower coefficients in pores. This adversely affects the kinetics of entrance and exit of macromolecules in and out of sorbent pores. Macromolecules consisting of many repeat units are, moreover, characterized by multi-centre adsorption, which makes the sorption-desorption process slower and more complex. Both these factors hinder interphase mass transfer and, hence, chromatographic zones become broader in the longitudinal direction. At the limit, tails and tracks appear on chromatograms in both adsorption and adsorptionless chromatography (Figures 1 and 2). In TLC both these factors become apparent as the mobile phase velocity is increased as a result of the increase of sorbent particle size. Hence, it must be borne in mind that in polymer analysis the eluent velocity is subject to greater limitations than in the analysis of low MW substances. To avoid the appearance of false zones and tails in polymer analysis, sorbents with a particle size of 5–8 μm must be used.

Specific properties of polymers are a consequence of the large size of their molecules. According to current concepts, a long flexible chain molecule in a dilute solution is coiled. The coil size is comparable to that of the pores. In the absence of adsorption the molecules enter the pore when the coil size is smaller than that of pores. When the coil size is too large, the molecule is excluded from the pore.

Even dilute polymer solutions are characterized by considerable viscosity, this viscosity increases with concentration and MW. The chromatographic zone forms a region with high viscosity, past which the mobile phase flows. This leads to an increase in the

size of chromatographic zones in the longitudinal direction (in the direction of mobile phase motion). Moreover, the longitudinal size of the zone increases both with concentration of the polymer in the zone and with increase in MW (Figure 2). Therefore, the shape of the polymer chromatographic zones is usually elongated in the direction of mobile phase motion, not only because of heterogeneity in MW and spreading as a result of slow interphase mass transfer, but also because of the viscous effect.

Polymers dissolve much more slowly than low MW compounds and their dissolution is preceded by swelling. Since, in TLC, dissolution precedes chromatography, the slower dissolution rate of polymers with high MW in the starting zone is manifested as tails on a plate at high eluent velocity (particle size 20 μm). Moreover, polymer solubility depends on MW, and the polymers usually become less soluble as MW increases.

The coil size (hydrodynamic volume) at a fixed MW is not constant. It depends on the thermodynamic quality of the solvent (thermodynamic quality expresses the measure of thermodynamic affinity of the solvent for the polymer) and also varies on passing from the mobile to the stationary phase.

There are several points of view about the mechanism of macromolecule adsorption. One view is that during adsorption the macromolecule diffuses from the solution into the sorbent pore, more or less retaining its globular shape. Another hypothesis states that in adsorption on the pore surface the molecule is uncoiled and lies flat on this surface. This becomes possible as a result of enthalpy gain when the chain segments interact with active centres on the sorbent surface. This gain exceeds the increase in the free energy because of entropy decrease. This process is accompanied by a considerable decrease in the

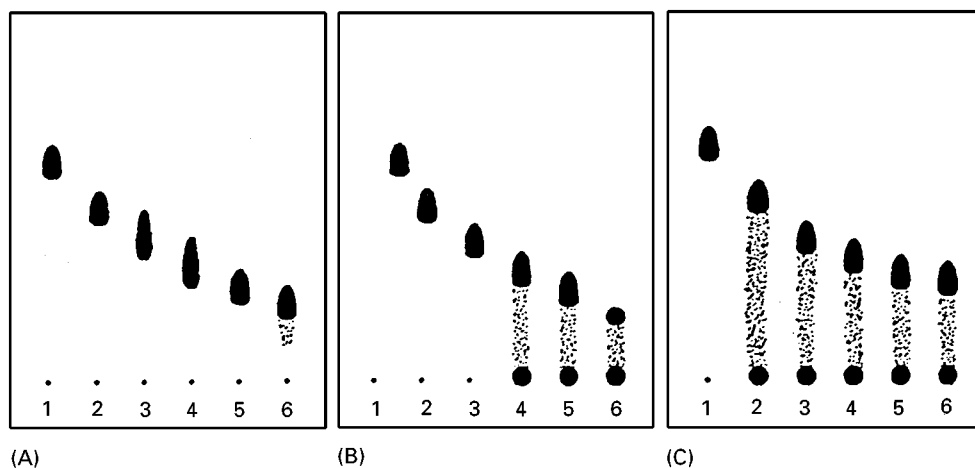

Figure 1 TLC of PS with MW (kDa) of (1) 20, (2) 111, (3) 200, (4) 498, (5) 865 and (6) 2610 on plates coated with silica gel KSKG with d_p (μm) of (A) 9.3, (B) 12.8 and (C) 19. Eluent: cyclohexane-benzene-acetone (12 : 1 : 1).

Figure 2 Adsorptionless TLC of PS with MW (kDa) of (1) 20, (2) 111, (3) 200, (4) 498 and (5) 867 on silica gel plates with sorbent particle size d_p (μm) of (A) 6.5 and (B) 19.0. Mobile phase: toluene.

volume occupied by the macromolecule, i.e. by an increase in density. As a result, the macromolecules are adsorbed on the surface of small pores inaccessible to them in a size-exclusion regime. Consequently, the change in free energy ΔG , when a macromolecule enters a pore is the sum of the change in entropy ΔS and enthalpy ΔH of the system ($\Delta G = \Delta H - T\Delta S$). The entropy change is caused by a decrease in the number of conformations of the macromolecule inside the pore over that in solution. The value of ΔH is due to the interaction of chain units with the pore walls.

It has been established experimentally, and confirmed theoretically, that in polymer chromatography the adsorption region and the molecular-sieve region are separated by a critical point at which the change in the conformational free energy of the macromolecule on passing from the mobile into the stationary phase is equal to zero. At this point the macromolecules undergo first-order phase transition. Under critical conditions homopolymers are not separated according to molecular weight; the pore structure of the sorbent and its specific area do not influence the behaviour of macromolecules. Hence, the number of separation mechanisms for polymers is greater than that for low MW compounds: besides adsorption chromatography ($-\Delta G > 0$, $k_d > 1$) at least two other chromatographic regimes are possible:

- $-\Delta G < 0$, $k_d < 1$ – size-exclusion chromatography (SEC);
- $-\Delta G = 0$, $k_d = 1$ – adsorption chromatography under the critical conditions (ACCC), where k_d is the distribution coefficient.

It is possible to pass from adsorption regime to size exclusion and vice-versa by varying temperature and

eluent composition or by modifying the adsorbent. These facts experimentally confirm a single mechanism of the liquid chromatography of polymers.

Chromatographic Regimes Applied to the TLC of Polymers

Adsorption–Exclusion Regimes

Adsorption TLC Adsorption TLC (ATLC) is used more extensively in polymer analysis. Enthalpy change is the dominant factor in the mechanism of adsorption separation of macromolecules. By selecting appropriate chromatographic conditions, adsorption activity of macromolecules can increase with increasing MW or the fraction of adsorption-active polar groups (for copolymers or homopolymers with functional groups).

ATLC is used to separate homopolymers according to their MW, functional groups and stereoregularity. It can also be used for the separation of copolymers according to composition and for the analysis of the MWD of oligomers with complete separation into oligomer homologues.

The most complex problem in ATLC is mobile phase selection. It is solved for the separation of homopolymers according to MW. In this case, the eluent for corresponding oligomer homologues is selected first (using, for example, the ‘Prizma’ model). Subsequently, a small amount of the adsorption-active component, the displacer, is added.

Exclusion TLC Entropy change is the dominant factor in the mechanisms of exclusion separation of macromolecules (ETLC). The chromatographic mo-

bility of macromolecules is determined by the ratio of the size of macromolecules to pore size and increases with the increasing hydrodynamic volume of the macromolecules. The exclusion effect is seen in TLC when two conditions are obeyed: the adsorption activity of the sorbent is suppressed and its pores are filled with the solvent. The interparticle volume should remain free. Pore filling can be accomplished either by pre-elution with subsequent removal of the solvent from the interparticle volume: the solvent passes along the plate before sample spotting; or else capillary condensation takes place during preliminary plate saturation with solvent vapour in a saturated chromatographic chamber. In the latter case the samples are spotted before saturation (or pore filling). Solvents or their mixtures in which analytes migrate along a dry sorbent layer with the front are used as eluents. The pore size distribution of the sorbent is of great importance and resolution in ETLC is lower than that in ATLC.

Adsorptionless TLC Adsorptionless (or viscometric) TLC is a type of exclusion TLC. It is carried out when the mobile phase moves along the dry sorbent layer. In this case the polymer is concentrated near the eluent front because the pores of the sorbent are accessible to it.

Moreover, a viscous polymer solution in the chromatographic zone plays the role of a kind of plug along which the solvent flows. Hence, the chromatographic zone acquires a droplike elongated shape and distinct boundaries. The zone length increases with both polymer concentration and its MW. For a fixed polymer quantity, the length of the chromatographic zone (L) is a function of intrinsic viscosity ($[\eta]$, at

infinite dilution). This dependence is obeyed for polymers of different nature, i.e. it is of universal character and can be obtained with the aid of any type of polymer standards (Figure 3). To determine $[\eta]$, it is necessary to plot the calibration dependence $L = f([\eta])$ by using four or five polymer standards in the required MW range at $C = \text{const}$. Subsequently, the length of the chromatographic zone is determined under the same conditions. Viscosity average MW value can be easily determined according to the Mark-Kuhn-Houwink equation with the aid of its coefficients available from reference books.

Adsorption TLC under critical conditions In adsorption TLC under critical conditions (ATLC), the changes in enthalpy during polymer interaction with the sorbent surface are compensated for by increasing entropy of the macromolecule when it enters the pore: $-\Delta H = T\Delta S$. ATLC under critical conditions is used to analyse heteropolymers: polymers and oligomers containing functional groups, block copolymers (AB and ABA types) and graft comb-like copolymers. Using ATLC it is possible to separate linear, cyclic and branched structures. In this regime one of the components of the copolymer undergoes chromatography under critical conditions and remains 'invisible' – having no effect on separation. Another component of the copolymer, the characteristics of which should be determined, takes part in the chromatographic process according to an adsorption or a size-exclusion mechanism. Critical conditions can be implemented either by using an adsorbent, the pores of which are filled with the eluent (analogously to ETLC) or by eluent migration along a dry sorbent layer. In the former case critical conditions are indicated by the absence of a separation according to MW for homopolymers with the same chemical composition as that component of the copolymer which should become 'invisible'. In the latter case the indication of critical conditions is the absence of separation (R_F values are equal) of homopolymers differing in MW but containing the same functional groups (Figure 4).

Figure 3 Dependence of zone length (L) on intrinsic viscosity for (1) PS, (2) PMMA, (3) polycarbonate, (4) polyisoprene (PI), (5) poly(vinyl chloride) and (6) poly(α -methyl styrene) with MW (kDa) of 20.8, 111, 200, 498, 867, and 2610 (1); 60.6 and 75 (2); 36.4 and 50.2 (3); 32.5 and 109 (4); 75 (5); and 97 and 610 (6) at a fixed polymer quantity (μg) of (I) 4 and (II) 10. Binder: gypsum; layer thickness, 500 μm .

Precipitation–Extraction Regimes

Precipitation TLC Precipitation TLC (PTLC) was first suggested and its mechanism investigated by Kamiyama and Inagaki in 1971. The classical examples are the separation of PMMA according to MW using a chloroform–methanol (29 : 71) mixture as the mobile phase.

In PTLC mixtures of polymer, solvent and adsorption-active precipitant (a thermodynamically poor solvent) are used as the mobile phase. Separation

Figure 4 ATLC of reaction mixtures, obtained by the reaction of PSLi with (1–4) methyl acetate, and (5) methyl benzoate; of tertiary alcohols (6) $(C_8H_{17})_2C(OH)CH_3$ and (7) $(C_8H_{17})_2C(OH)C_6H_5$, of (8) polymer ketone $PS-CH_2-C(C_6H_5)_2-COCH_3$ and its PS precursor with MW 0.4 kDa and PS standards with MW (kDa): (9) 0.4 and (10) 40. Reaction mixtures (1–5) contain: PS precursors with MW (kDa): (1, 5) 0.4, (2) 0.6, (3) 6.4 and (4) 13.5, polymer ketone $PS-CO-R$ with the same MW as that of PS precursors, and tertiary polymer alcohol $(PS)_2C(OH)-R$ with double MW, where R is $-CH_3$ or $-C_6H_5$. Conditions are close to the critical point for PS: adsorbent is silica gel KSKG; mobile phase is toluene- CCl_4 (1 : 4) mixture.

occurs as a result of changes in the dissolution properties of the mobile phase along the chromatographic plate, for instance, as a result of partial evaporation of mobile phase components demixing during chromatography. The dissolution properties of the mobile phase can also be changed by delivering it with a changing composition to the plate. The initial mobile phase should contain the adsorption-active component at a concentration completely preventing polymer adsorption.

During PTLC when the individual polymer species with different MW pass along the plate they undergo a continuous series of precipitations and extractions. The elementary PTLC process is the separation of a polymer solution into the dilute phase, which is transported with the solvent flow, and the concentrated gel phase which is precipitated on the surface of sorbent particles.

PTLC is used to separate homopolymers and random copolymers by MW and to separate a block copolymer from the corresponding homopolymers. The analysis of oligomers with the aid of PTLC is not effective. The working range of MW exceeds 10 kDa.

Extraction TLC The action of extraction TLC is opposite to that of precipitation TLC. Extraction TLC is based on selective dissolution and desorption of the polymer in the starting zone region. Desorbed

polymer fractions are displaced to the eluent front. Eluent migration length is not significant. Polymer zones move along the plate in size-exclusion mode. Since the eluent moves along a dry sorbent layer, separation according to MW does not take place. In this method a single component mobile phase or binary solvent mixtures are used most often; gradient column chromatography is the closest analogue. Under conditions of extraction TLC the gradient is replaced by stepwise elution.

Using extraction TLC it is possible to separate compounds differing essentially in solubility or adsorption activity: isotactic and atactic polystyrene, isotactic and atactic PMMA, poly-1,4 trans- and 1,2-butadiene and to separate the S-MMA block copolymer from PS and PMMA.

Some Problems in Polymer Analysis

Determination of MW and MWD TLC, like other chromatographic methods, is not an absolute method. Therefore, in order to determine physical or chemical heterogeneity, polymer standards with known characteristics are necessary. Belenkii and Gankina state that in order to determine the MWD, it is necessary first to establish the dependence of R_F on MW with the aid of narrow-disperse standards, secondly to obtain a densitogram of the chromatographic zone, thirdly to establish the dependence of the recorded signal (I) on polymer mass (P) for different R_F s and to determine $(dP/dI)_{R_F}$, fourthly to determine the distribution of polymer mass in the zone $P(R_F)$, and finally to calculate MWD according to the following equation:

$$P(M) = P(R_F) \left(\frac{dM}{dR_F} \right)_{R_F}$$

If the distribution, $P(M)$ is known, it is also possible to obtain the expressions for weight-average MW

$$\bar{M}_w = \frac{\int_0^\infty M^2 P(M) dM}{\int_0^\infty M P(M) dM}$$

number average MW:

$$\bar{M}_n = \frac{\int_0^\infty M P(M) dM}{\int_0^\infty P(M) dM}$$

and heterogeneity:

$$H = \frac{\bar{M}_w}{\bar{M}_n}$$

An important point increasing the precision of MWD determination is the correction for instrumental broadening in SEC. This is attained with the aid of

two-dimensional chromatography. In the first direction the chromatographic zone is separated according to MW and also undergoes chromatographic spreading. In the second direction the separation according to MW may be neglected. The dispersion of chromatographic spreading is equal to the difference between zone dispersion after the second and the first elution in the direction of the second elution. For correction, the calculated dispersion of chromatographic spreading is subtracted from the total dispersion of the polymer zone after the first elution in the direction of mobile phase migration.

Analysis of Copolymers

As polymer molecules very often contain functional groups or consist of chains differing in chemical nature, polymers are characterized by a mixed separation mechanism. The analysis of copolymers exhibiting chemical and structural heterogeneity requires more complex elution procedures: for example, stepwise, two-dimensional, gradient and continuous TLC. In most cases TLC is combined with column chromatography or pyrolysis-gas chromatography (GC), as well as with spectroscopic methods.

In the analysis of block and graft copolymers or branched homopolymers, the following problems should be solved:

- the diagnosis of a copolymer or a branched homopolymer;
- the determination of linear homopolymer present in the copolymer; and
- the investigation of MW and MWD of copolymers.

The first two problems can be solved by comparing the chromatographic mobility of the polymer being analysed with that of the corresponding linear homopolymers in appropriate solvents using ATLC or PTLC. An indispensable condition of separation is the difference in adsorption activity or solubility of A and B homopolymers. Difficulties can appear if their properties are similar and also when block copolymer complexes with one of the homopolymers are formed.

Additional proofs of copolymer presence can be obtained by double detection of the chromatographic spots, for example, by using reagents specifically staining homopolymers of different types and by spectroscopic methods *in situ*, or after elution of the polymer zone from the plate.

To evaluate the MW of block-copolymer components, one can use ATLC under critical conditions.

Oligomers

Oligomers are built from the same monomer units as polymers, but their chain is much shorter

(MW < 10 kDa). Polymers in dilute solutions are characterized by the following types of interactions: solvent-solvent, solvent-polymer segment, polymer segment-segment, solvent-surface, and polymer segment-surface, whereas for oligomer segment-segment interaction and local entropy effects are small. Oligomers without end groups are readily separated into oligomer homologues on polar adsorbents by adsorption chromatography. It is also easy to separate according to MW, oligomers with end groups for which the energies of interaction with adsorbent for the central (ϵ_c) and end (ϵ_e) units are similar. If the energy of interaction with silica gel is much lower for the central chain unit than for the end groups ($\epsilon_c < \epsilon_e$), separation according to the types of functionality will take place. Therefore, to separate according to MW it is necessary to use silica gel modified either chemically (for example, RP₁₈) or dynamically (for example, the separation of PEO oligomers in a pyridine-water mixture, 0.1 : 10).

Two-component mobile phases are known to separate some oligomers according to MW on silica gel: PS, PI, poly(propylene glycol), PEO and its various derivatives, oligoacrylates, etc. If the MW of one of the members of the homologous series on the chromatogram is known, corresponding standards are not necessary to calculate MWD.

For oligomers used in the production of synthetic polymers, the distribution according to the types of functionality (FTD) is very important. It characterizes the relative content of macromolecules with different functionalities in the oligomer. The functionality type of chemical compounds is determined by the number and nature of functional group. For macromolecular compounds the concept 'functionality' just as the concept 'molecular weight' has a statistical significance. In order to characterize distribution width according to functionality types the values of number-average (\bar{f}_n) and weight-average (\bar{f}_w) functionality are used:

$$\bar{f}_n = \sum n_i f_i / \sum n_i$$

$$\bar{f}_w = \sum n_i f_i^2 / \sum n_i f_i$$

where $n_i = p_i / MW_i$ (is the number of moles of macromolecules i with molecular weight MW_i , functionality f_i and weight p_i).

Oligomers are separated according to the number and nature of functional groups by adsorption chromatography under the critical conditions or under conditions close to critical. An example of this separation is shown in Figure 4. A scanning densitometer or a videodensitometer can be used for quantitative FTD determination.

Future Developments

TLC of polymers is more complex than that of small molecules for the following reasons: the size of sorbent pores and that of macromolecules are similar and co-operative effects exist which are characteristic of macromolecules as multcentred formations. For the same reasons, TLC of polymers is a very useful technique to investigate chromatographic mechanisms. The open sorbent layer in TLC makes it much easier to detect and investigate chromatographic artefacts than by column chromatography. The versatility of this method, the absence of restrictions with respect to solvents, and high sensitivity to functional groups (ATLC) make it possible to analyse effectively the compositional and structural heterogeneity of polymers.

Further development of this method involves investigations of mechanisms of adsorption and chromatography of macromolecules, more extensive use of chemically modified sorbents, more extensive application of quantitative methods of analysis and such promising methods as overpressured-layer chromatography (OPLC). The investigation of macromolecules with complex architecture and of reaction mixtures is not possible without perfecting complex methods of investigation. The combination of ATLC and column chromatography in different regimes and the combination of TLC with spectroscopic methods, especially with MALDI-TOF-MS are very promising.

Introduction

Essential oils are secondary metabolites of plant origin and are complex mixtures of fragrance and

flavour substances. They originate in roughly one-third of known plant families and are isolated from plant bodies by extraction or distillation procedures. The composition of the constituents are dependent on the isolation method used, the part of the plant body from which they are isolated and also on their thermal, pH and intrinsic chemical stability. Most essential oils are currently separated from nonvolatile materials by steam distillation. As for other classes of natural products, a fully satisfactory definition of essential oils is difficult to put into words. Although they are volatile plant materials, they do not leave a grease stain on paper.

* Retired. Present address: Camlin Limited, Pharmaceutical Division, Camlin House, J. B. Nagar, Andheri (E), Mumbai 400 059, India.

Terpenoids in Essential Oils

The majority of the essential oils of commercial interest are mixtures of mono- and sesquiterpenoids, containing only minor amounts of compounds belonging to other classes. The second largest group of essential oils consists of aromatic compounds including phenolic ones. The terpenoid components occur admixed with the corresponding terpene hydrocarbons, which generally contribute less to the aroma component. Among the popular essential oils are bergamot, grapefruit, lemon, lime, mandarin, orange, petitgrain and neroli oils belonging to the citrus class of oils. These oils contain varying proportions of different types of monoterpenoids, e.g. linalyl acetate, linalool, citrals (geranial and neral), corresponding acetates, and nootkatone. Lime oil, one of the most important distilled citrus oils contains 1,4- and 1,8-cineole, terpinen-4-ol and α -terpineol, along with aromatic p-cymene, which is probably derived from limonene by oxidation. Another important class of essential oils is cedar oils, which are characterized by the sesquiterpenoids cedrol, cedryl acetate, cedrene, thujone, thujopsene, *trans*- α -atlantone and the monoterpenoids pinenes and delta-3-carene along with 2-*trans*-4-*cis*-decadienyl isovalerate. A major class of essential oils derived from the plant class *Eucalyptus* has about 500 species. Monoterpenoids such as citronellal, citronellol, isopulegol, piperitone and β -phellandrene are the important constituents apart from geraniol and nerol. See [I]–[VII] for structures of some of these components of essential oils.

Other important essential oils are grass oils, e.g. lemon grass oil containing citral, geraniol, etc. Vetiver oil has high sesquiterpene content of α and β vetivone.

Lavandula oils contain linalool and linalyl acetate in the lavender oil variety whereas lavandin oil contains camphor and 1,8-cineole. Essential oils of the mentha variety are characterized by the presence of menthol, menthone and menthyl acetate. Spearmint oil of the mentha variety contains carvone, dihydrocarveol, menthone and limonene. Pulegone is also found in the mentha variety of oils. Balsam and wood terpentine oils contain bornyl acetate along with pinenes, limonene, p-menthadienes, whereas the Sage oils class of essential oils contain sclareol and α - and β -thujones.

There are other varieties of essential oil containing terpenoids, e.g. ambrette seed oil; amyris oil containing sesquiterpenoids, e.g. elemol, eudesmols and α -agarofurans. Buchu leaf oils contain menthone, isomenthone, pulgione and bifunctional diosphenols also known as 'buchu camphors' and some sulfur-containing terpenoids, e.g. p-menthane-8-thiol-3-one and its thioacetate. The plethora of essential oils containing mono- and sesquiterpenoids occurring in nature is extremely large and a description of the principal constituents in them is beyond the scope of this chapter. Among the oils having importance in the perfumery industry, rose oil contains damascenone, *cis*-rose oxide and verbenone in various species; sandalwood oil contains the santalols; rosemary oil contains verbenone; patchouli oil has patchoulol and norpatchoulol; orris root oil contains neoiso- α -irone; jasmin oil contains *cis*-jasmone and methyl jasmonate; guaiac wood oil contains guaiol; and costus root oil contains costol and dehydrocostuslactone.

Among the essential oils used as food flavouring, ginger oil contains the zingiberenes, *ar*-curcumen and β -sesquiphellandrol, copaiba (balsam) oil con-

tains caryophyllene, celery seed oil contains β -selinene, cardamom oil has 1,8-cineole and α -terpinyl acetate. Some tea aroma components are presumed to be derived partly from the ionone series of compounds (probably derived from carotene besides other terpenoids such as methyl jasmonates, which give the sweet taste to Oolong tea leaves.

Essential oils also have therapeutic significance, e.g. in antiseptics and antibacterials, analgesics (clove, peppermint, lavender, birch oils), anti-fungals (tea tree, thyme), anti-inflammatories (German chamomile, lavender), anti-toxics (chamomile oil), anti-virals (*Melissa officinalis*, *Eucalyptus smithii*, *Ravensara aromatica*, *Niaouli*), diuretics (juniper oil), balancers, deodorants, digestives (anise, caraway, peppermint, lavender), spasmolytics (basil, majoram, German chamomile, cypress, laurel), mucolytics and expectorants (*Eucalyptus globulus*, pine, anise, thyme). They are also used as insecticides and insect repellents (citronella, cinnamon, geranium). See structures [VIII]–[XXIV] for some components of therapeutic essential oils.

Analysis of Essential Oils

The economic importance resulting from their fragrance and aroma which is used extensively in the perfume and food flavour industries as well as the therapeutic applications requires that reliable analytical methods are available for qualitative and quantitative analysis of the individual ingredients as well as methods for their preparative separation from the complex mixtures they exist in. In fact, most varieties of essential oils are so complicated that resolution and analysis of any single component of interest is a formidable task. Although liquid and gas chromatographic separations on analytical and preparative scales have been used, such techniques are plagued with the problems of weak UV absorbance, volatility and thermal instability of many of the ingredients. Most of the essential oils contain only very minor amounts of the active principles and large amounts of undesired components that obscure the separation and reduce the sensitivity. The important developments that have taken place in liquid chromatographic analysis of essential oils over the years are

discussed later. Before attempting any liquid chromatography (LC) or gas chromatography (GC) analysis, the terpene hydrocarbons are usually removed by distillation because of their considerably lower odour and aroma values. Furthermore, these olefins polymerize and are poorly soluble in lotions.

Thin-Layer Chromatography

Thin-layer chromatography (TLC) is an inexpensive technique and was the earliest LC method used to provide information on the complexity of essential oils. TLC studies of thymus essential oil on SiO_2 plates using various developing solvent systems and detection by spray reagents, e.g. H_2SO_4 charring, could identify thymol and carvacrol as the essential components by comparison with standard substances. This TLC method has been further employed to quantify these components by scanning densitometry. Additionally, quantification of geraniol, citral, terpinen-4-ol, cineole and gamma-terpinol have been carried out on thymus essential oil. Coscia described various reagents used to quantify mono-, sesqui- and other terpenoids (also polyphenols) such as carotenoids, tocopherols, retinoids, etc. in analysis of essential oils by TLC.

HPLC Analysis of Essential Oils

Almost 90% of the components present in essential oils that are responsible for fragrance and flavour are in the boiling range of 150–300°C and possess ideal vapour pressure to be successfully analysed by gas chromatography. The molecular weights of these

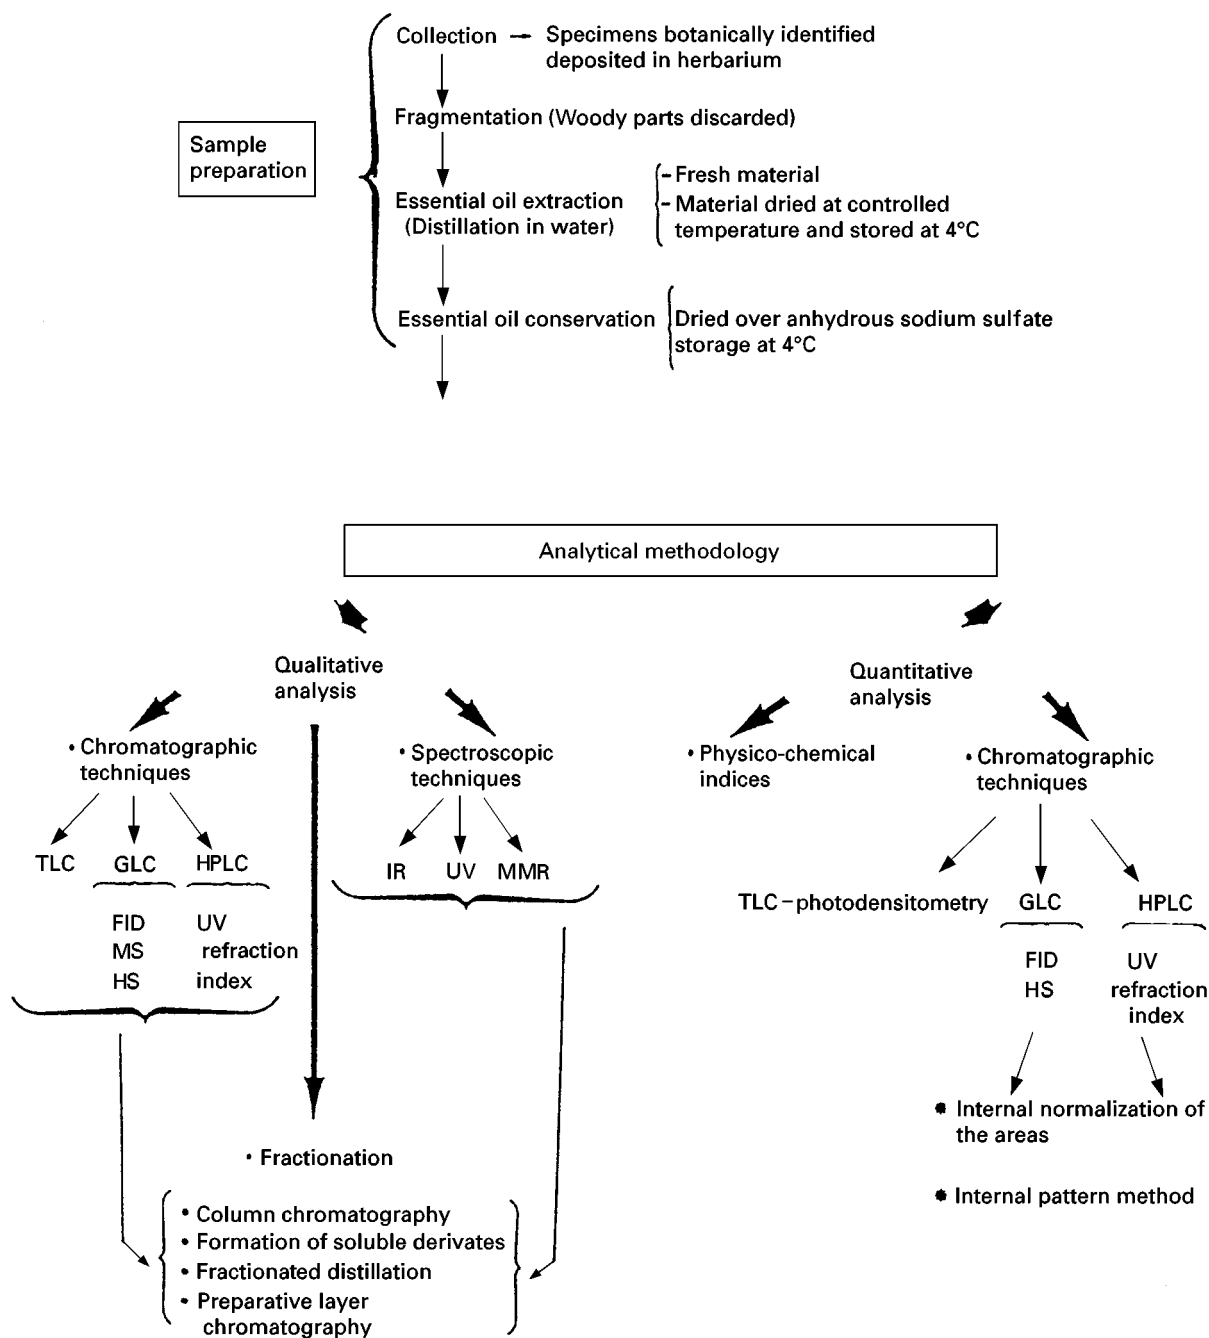

Figure 2 General protocol recommended for the identification and quantification of essential oil components. (Courtesy, Springer-Verlag GmbH and Co.)

compounds are mainly in the range up to 300 amu, thus making GC-MS an ideal technique for analysis and identification. However HPLC is being used increasingly to analyse essential oils (Figures 1–4) and in fact HPLC shows certain significant advantages over currently used open tubular column GC methods, such as minimal exposure to air, the avoidance of high temperature degradation, ease of separ-

ation of nonvolatile components and higher sample recovery. Furthermore, although as mentioned earlier, a majority of the terpenoids are weakly absorbing in the ultraviolet (UV) region due to the lack of a chromophore, the availability of highly sensitive online ultraviolet-visible (UV/Vis) detectors has expanded the utility of high performance liquid chromatography (HPLC) applications in essential oil

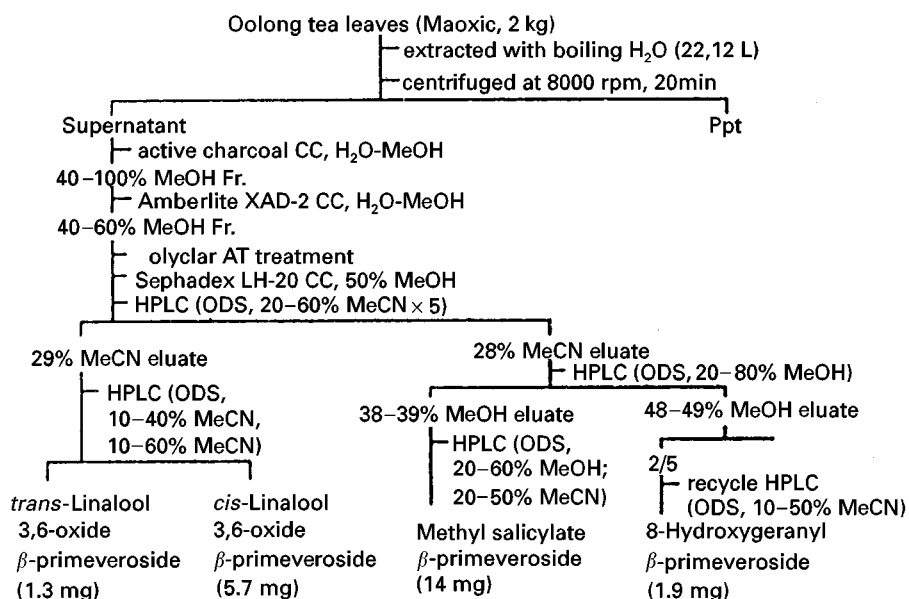

Figure 3 Isolation procedure of aroma constituents from Oolong tea.

analysis. The problem of UV detection on normal phase columns using eluents that are strongly UV absorbing has been largely alleviated by using reversed-phase columns which permit the use of solvents

like methanol and acetonitrile, and detection by end absorption, i.e. between 200–220 nm. Although differential refractive index (RI) and polarimetric detectors have been used, they suffer from poor sensitivity. Polarimetric detection is however claimed to have better selectivity. Pulsed electrochemical detectors have been used for flavour-active alcohols by Le Fur. Primary terpenols are detectable at ppb level with others at ppm level. Primary and secondary alcohols can be quantified with good repeatability and sensitivity.

Since essential oils are highly complex mixtures; HPLC is of great assistance for both the separation of the components into classes and of such a class into its components. Such pre-fractionation is followed by subsequent high-resolution GC (HRGC) analysis of the fractions. Multiple LC separations have been frequently carried out in tandem in order to obtain adequate pre-fractionation before subjecting each fraction to GC analysis. Thus the labile sesquiterpene germacrene B has been isolated by Clark from lime peel oil as an important flavour impact component. Various types of HPLC columns have been used, e.g. normal phase, diol-bonded silica and reversed phase, e.g. C2, C4, C8 and C18. In one example strawberry jam was previously gel filtered through Sephadex LH-20 to remove fatty acids. The resulting material was subjected to gradient HPLC using a diol-bonded silica column and gradient elution using pentane-diethyl ether resulting in two major fractions, the first containing hydrocarbons, esters, aldehydes and ketones and the second fraction consisting of polar

Figure 4 Isolation procedure of linalyl β-vicianoside, bornyl β-primeveroside, and 2'-phenylephenylthyl β-primeveroside from *Gardenia jasminoides*. (Figures 3 and 4 – Reproduced from *The International Congress of Flavours, Fragrances and Essential Oils*.)

compounds such as alcohols, hydroxy esters and lactones. GC-MS analysis of these fractions identified 150 compounds as compared to only 60 in the absence of HPLC pre-fractionation. Computer-controlled online HPLC-HRGC has thus emerged as a powerful method for essential oil analysis. Munari used a fully automated HPLC-GC instrument for HPLC pre-separation of citrus oil into four major fractions – hydrocarbons, aldehydes, esters and alcohols – using gradient elution, and the fractions were automatically transferred to the GC. HPLC pre-separation with multiple GC transfer from a single HPLC injection combined with other identification techniques, e.g. mass spectrometry (MS), Fourier transform infrared (FT-IR) spectrometry gives additional advantage of online identification. The most widely used among such techniques is high performance liquid chromatography-gas chromatography-mass spectrometry (HPLC-GC-MS). This technique has been used in a fully automated form by Mondello for the analysis of several essential oils: bergmot, lemon, clementine, sweet orange, bitter orange, grapefruit and Mexican lime. The information was more accurate than that obtained by only GC-MS analysis of the essential oil. Using chiral GC columns Giovanni determined the enantiomeric distribution of the monoterpene alcohols in citrus essential oils. In the same vein it can be envisaged that such multidimensional techniques as microbore HPLC-electrospray ionization/MS-MS holds great potential in essential oil analysis since in addition to improved column efficiency, the second mass analyser permits mixture analysis by interpretation of the collision activated dissociation (CAD) spectrum obtained.

Separation of Enantiomeric Components

The terpenoids present in essential oils are chiral molecules occurring in enantiomerically pure form. HPLC analysis using chiral columns and co-elution with authentic optically pure compounds furnish information on the chirality of the constituents. HPLC separation of enantiomeric mixture of α -pinene, β -pinene, camphene and limonene were carried out by Moeder on a C4 column with UV detection at 210 nm and a mobile phase containing 5–20 mM of α -cyclodextrin, or 0.01–0.8 mM of β -cyclodextrin (90:10 mixture of MeOH and 0.1% phosphoric acid). Equations were derived for the apparent formation constants of the diastereoisomeric complexes of the solute with cyclodextrin and their stoichiometry estimated. It was observed that efficient separation was achieved with only α -cyclodextrin for these bicyclic terpenes. Chiral discrimination of enantiomeric

derivatives of α -pinene has been achieved using amylose *tris*(3,5-dimethylphenyl)carbamate as the chromatographic stationary phase. The major contributing factor to achieve such separation is H-bonding of the analytes with the carbamated amylose.

Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) has also been used for the separation of terpenoid compo-

(Courtesy Kluwer Academic Publishers, The Netherlands.)

nents. The advantage of SFC lies in the fact that it has features of both GC and LC. Both GC and LC columns can be used and various detectors like flame ionization detector (FID), UV and MS can be used making it a nearly universal technique. To illustrate the application of SFC 2-Z- and 3-E-nerolidols, R/S-geranyliol, α -bisabolol and 2E,6E-fernesol were separated in 10 min on a column packed with 5 μ m Zorbax Z215 silica equipped with a guard column of the same material operated at 40°C with CO₂ containing 0.5% MeOH as the mobile phase and monitoring the components at 220 nm. In another example eight terpene components of cinnamon oil were separated on a delta-bond SiO₂ column at 125°C using a gradient elution of 100% CO₂ to 7% EtOH in CO₂. The detection limits were typically 1.0 μ g mL⁻¹ for the terpenes with a linear response over four decades.

Preparative Liquid Chromatography

Isolation of individual essential oils is a formidable task because of their complexity. Open column chromatography, droplet countercurrent chromatography (DCCC), rotation locular countercurrent chromatography (RLCCC) and gel permeation chromatography are some of the techniques which

have found considerable use. However each of these techniques has its weaknesses. Multiple separations on either normal- or reversed-phase packing materials (40–70 μ M) using low to medium pressure (10–40 bar) accomplishes substantial enrichment of the components in terms of their functional group type and/or polarity. Using step or gradient elution techniques the complex mixtures of terpene hydrocarbons, carbonyl compounds, alcohols, esters, etc. can be cut into fractions. Online UV detection and automatic fraction cutting considerably enhances the utility of such medium pressure liquid chromatography–low pressure liquid chromatography (MPLC–LPLC) techniques. The fractions can then be subjected to preparative HPLC using columns of inner diameter >10 mm to furnish the semipure components. Even preparative HPLC may have to be repeated several times before adequate resolution is achieved. The pooled fractions are then subjected to semi-preparative HPLC (column i.d. <10 mm) followed by peak collection from analytical columns to yield the pure terpenoids. The level of purity desired depends on the use for which the component materials are required. Some representative HPLC traces for the separation of essential oil components are shown in Figures 5–7. In several cases where the terpenoids exist as glycosides or some such deriva-

tives, pre-purification using other forms of liquid chromatography like hydrophobic interaction chromatography on HP or XAD types of resins is done followed by separation of individual compounds on a reversed-phase HPLC column. Two such examples are the separation of linalyl β -vicianoside, bornyl β -primeveroside and 2-phenylethyl β -primeveroside from *Gardenia jasminoides*. Separation of *cis*-linalool 3,7-oxide-6-O- β -D-apiofuranosyl- β -D-glucopyranoside from oolong tea leaves was achieved using similar methodology.

Conclusion

In view of the importance of essential oils in the perfume, food and flavour industries as well as their therapeutic applications, it is imperative that research in their analysis and isolation continues. The crux of the problems associated with such endeavours lies basically in the fact that the constituents of essential oils most often occur in very minor amounts. Therefore the aim of further analytical research has to be directed to the achievement of the highest possible sensitivity and resolution. HPLC analysis using micro

columns containing either normal- or reversed-phase silica as packing material coupled to detectors like the electrospray ionization mass spectrometer with ion-trap detectors permitting MSⁿ analysis holds good potential. Electroanalytical techniques like capillary electrophoresis can go a long way in both qualitative and quantitative analysis of essential oil constituents. Capillary electrophoresis interfaced with MS and/or a photodiode array detector is likely to solve the problems of separation complexity of essential oil components.

THERMALLY-COUPLED COLUMNS: DISTILLATION

R. Smith, Centre for Process Integration, UMIST, Manchester, UK

Copyright © 2000 Academic Press

Introduction

A considerable amount of energy is used in distillation operations. Energy integration has proven to be successful in reducing energy costs for conventional distillation arrangements. However, the scope for energy integration of conventional distillation columns into an overall process is often limited. Also, practical constraints often prevent integration of distillation columns with the rest of the process.

If the column cannot be integrated with the rest of the process or, if the potential for heat integration is limited by the heat flows in the background process, then we must turn our attention back to the distillation operation itself and look at unconventional arrangements.

Figure 1 shows two conventional arrangements for the separation of a three-component mixture. The sequence shown in Figure 1A is the so-called direct sequence, in which the lightest component is taken overhead in each column. The indirect sequence shown in Figure 1B takes the heaviest component as bottom product in each column.

One of the most significant unconventional arrangements involves thermal coupling. Figure 2 shows a number of unconventional arrangements that use thermal coupling. In thermal coupling part of the heat transfer necessary for the separation is provided by direct contact via material flows. Figure 2A shows a side-rectifier arrangement and Figure 2B a side-stripper arrangement. Arrangements similar to that in Figure 2B are widely used in petroleum refining. The fully thermally coupled arrangement in Figure 2C (sometimes known as the Petlyuk column) has been known for over 50 years. Various studies have shown that thermally coupled arrangements can

save up to 30% of energy costs when compared with conventional arrangements.

Simple Versus Complex Columns

Consider first the design of distillation systems comprising only simple columns. These simple columns employ:

- one feed split into two products;
- key components which are adjacent in volatility;
- a reboiler and a condenser.

For a three-component mixture in which simple columns are employed, the decision is between the two sequences illustrated in Figure 1.

Consider the first characteristic of simple columns, which involves a single feed being split into two products. As a first option to two simple columns, the possibilities shown in Figure 3 can be considered, in which three products are taken from one column. The designs can be both feasible and cost-effective when compared with simple arrangements, but only for certain conditions. If the feed is dominated by the middle product (typically more than 50% of the feed) and the heaviest product is present in small quantities (typically less than 5%) then the arrangement shown in Figure 3A can be an attractive option. If a pure middle product is required, then it is usually only possible if there is a large volatility difference between components B and C, with the middle product taken as a vapour to assist the separation. The heavy product must find its way down the column past the side-stream. Unless the heavy product has a small flow and the middle product a high flow, a reasonably pure middle product cannot be achieved.

If the feed is dominated by the middle product (typically more than 50%) and the lightest product is present in small quantities (typically less than 5%), then the arrangement shown in Figure 3B can be an attractive option. This time the light product must find its way up the column past the side-stream. If

THE NUCLEAR INDUSTRY: ION EXCHANGE

J. Lehto, University of Helsinki, Helsinki, Finland

Copyright © 2000 Academic Press

Introduction

Ion exchange is used in nearly all phases of the nuclear fuel cycle beginning in the early stages of uranium ore treatment where ion exchange is one of the major processes used: uranium is removed from ore leach liquors using anion exchange resins.

At nuclear power plants, ordinary organic ion exchange resins are mainly used for the removal of ionic and particulate contaminants from the primary circuit, condensate and fuel storage pond waters. Ion exchange resins are also used for the solidification of low- and medium-activity nuclear waste solutions. The number of applications of selective inorganic ion exchangers in the separation of radionuclides from nuclear waste solutions has been increasing since the mid-1980s.

In nuclear fuel reprocessing plants, the main separation method is solvent extraction. Ion ex-

change is, however, used for the solidification of low- and medium-activity waste solutions, as well as for the partitioning of radioactive elements for further use.

This article reviews all the most important areas of the utilization of ion exchangers in the nuclear power industry. Special attention is paid to ion exchange processes, which involve radionuclide removal functions, and to new developments in selective ion exchange materials.

Ion Exchange Materials Used in the Nuclear Industry

Nuclear Grade Ion Exchange Resins

Organic ion exchangers used at nuclear power plants are based on conventional poly(styrene-divinylbenzene) resins with sulfonic acid ($-\text{SO}_3^-$) and quaternary ammonium ($-\text{N}(\text{CH}_3)_3^+$) functional groups for cations and anions, respectively. Nuclear grade resins,

however, have to meet higher quality requirements than those used in most other industries.

First of all, the purity levels of nuclear grade resins have to be very high and, in particular, leachable corrosive impurities such as chloride and sulfate in anion exchange resins should be avoided. Second, nuclear grade resins should have high levels of the desired ionic form. For example, cation exchange resins in the hydrogen form, used in mixed beds for demineralization, should not contain a high proportion of sodium ions because they become activated in the neutron flux of the primary circuit and increase the radiation field. The content of heavy metals should also be very low. Thus, nuclear grade cation exchange resins are usually a minimum of 99% purity in the hydrogen form and typically the sodium and iron contents are below 0.01% and the contents of other metals even lower. ^7Li -form resins, used in some pressurized water reactors, have a 99% minimum purity in the lithium form. Nuclear grade anion exchange resins have a 95% minimum in the OH^- form, the rest being mainly in the CO_3^{2-} form. The contents of chloride and sulphate in anion exchange resins are typically very low, less than 0.1% and 0.3%, respectively. In addition to a high purity and a high level of desired ionic form, nuclear grade resins are more uniform in particle size compared with conventional resins and the amount of fines is very low.

Organic ion exchange resins are used in nuclear plants in two ways (Figure 1). First, as deep beds, i.e. columns packed with bead form resins. The volume of a bed is typically $1\text{--}2\text{ m}^3$ and the bead size 20–50 mesh. Their second use is as pre-coat filters, i.e. inert filters coated with a layer of crushed anion-cation resin mixture; the layer thickness is typically 5 mm and the particle size 200–400 mesh. Pre-coat filter systems are mainly used in the purification of solutions that contain high proportions of solid matter.

Inorganic Ion Exchangers

Use of inorganic ion exchangers at nuclear plants has been increasing since the mid-1980s. Utilization has been limited in nuclear waste management processes where the main advantage of inorganic ion exchangers over organic exchangers has been their superior selectivities to certain radionuclides. Other advantages are their resistance to radiation and high temperatures. The main problems which have hindered installation of inorganic ion exchange materials have been that they have not been available in stable grains or granules suitable for use in packed bed columns and that many of them are not chemically stable in high or even moderate acidities and alkalinities. As will be seen below, some of these problems have been overcome in the last 10 years.

Ion Exchange in the Processing of Uranium Ores

Uranium ores are first ground into submillimetre particles and uranium is leached out with sulfuric acid. If the ore contains a large quantity of acid-consuming CaCO_3 , leaching is carried out with sodium or ammonium carbonate solution. In sulfuric acid and carbonate solutions, uranium forms soluble sulfate and carbonate complexes, predominantly $\text{UO}_2(\text{SO}_4)_3^{4-}$ and $\text{UO}_2(\text{CO}_3)_3^{4-}$. These anionic complexes are removed from leach liquor with strongly basic anion exchange resins. For further processing, uranium sulfate is eluted from resin with dilute ($0.1\text{--}1.0\text{ mol L}^{-1}$) acid solutions. In the case of carbonate leaching, elution from the resin is carried out with dilute sodium chloride or ammonium nitrate solutions instead of acid to prevent formation of carbon dioxide in the column.

Figure 1 Typical deep bed (A) and pre-coat filter (B) units used at nuclear power plants.

Ion Exchange Processes at Nuclear Power Plants

Ion exchangers are utilized for many purposes at nuclear power plants (NPP):

- Purification of primary coolant water
- Control of primary coolant water chemistry
- Polishing of steam condensate
- Production of make-up water
- Purification of spent fuel storage pond water
- Treatment of waste solutions.

Most of these processes are used in all types of nuclear power plants. Purification of the primary coolant by ion exchange is, of course, not necessary in gas cooled reactors. Control of primary coolant chemistry applies only to some pressurized water reactors (PWR), using both light and heavy water as a moderator/coolant. Polishing of steam condensates is important in all reactor types but only in boiling water reactors (BWR) does it play an important role in removing radioactive contaminants. The two Finnish nuclear power plants, Olkiluoto NPP and Loviisa NPP, are given below as examples of installations using typical ion exchange systems for boiling water and pressurized water reactors. Loviisa NPP uses some 15 tonnes of ion exchange resins per annum and Olkiluoto NPP 22 tonnes.

Purification of Primary Coolant Water

In nuclear power reactors the primary coolant water is circulated from the reactor vessel to the steam generator (PWR)/turbine (BWR) and back. In BWRs the primary coolant is pure water but in PWRs it also contains boric acid, which is used as a moderator to slow down the neutrons and LiOH or KOH to adjust the pH. Primary coolant water contains radioactive components in ionic and particulate form and these have to be removed to prevent the build-up of excessive radiation fields. There are two types of radioactive contaminants in the primary circuit: fission products originating from leakages from the fuel elements, the most important of these nuclides being ^{137}Cs , and activated corrosion products from reactor materials, of which ^{60}Co and ^{63}Ni are usually the most important (^{51}Cr , ^{54}Mn , ^{58}Co and ^{65}Zn can be found as well). Caesium exists in solution in ionic form and the corrosion products are mainly in the form of particles. In the removal of these radioactive contaminants, ion exchange resins work both as ion exchangers and as mechanical filters.

The exhaustion of the ion exchangers in all the processes at nuclear power plants is determined by one of the following parameters:

- Increased conductivity in the effluent
- Increased radioactivity in the effluent
- Increased pressure drop.

Especially in the processes where large amounts of solid fines are to be removed, increased pressure drop is the dominant parameter.

At the Olkiluoto NPP, which has two 710 megawatt (MW) BWRs, primary circuits are purified with two parallel deep bed units each of 1.5 m³ volume. The beds consist of equal quantities of cation and anion exchange resins. The function of the ion exchange purification system is to remove all ionic contaminants. The resins are initially in the H⁺ and OH⁻ forms and they demineralize water as shown in eqn [1].

where R is the resin matrix. The temperature of the water (270°C) has to be lowered to 60°C before conveying it into the ion exchanger bypass. The flow through each unit is about 2% of the total flow. Resins are replaced twice a year and solidified, without regeneration, with bitumen in the ratio of about 1:1 for final disposal.

At the Loviisa NPP, which has two 440 MW PWRs, the primary circuits are purified by two independent ion exchange systems. The first one is a deep bed having 1 m³ of equal amounts of cation and anion resins. The second system consists of two beds, of 1 m³ each, one being a cation exchanger and the other an anion exchanger. In both systems the exchangers are initially loaded in H⁺ and OH⁻ forms but in the early stages of the run they reach equilibrium with ions in the coolant water. The cation exchanger is converted into the H⁺/K⁺/NH₄⁺/Li⁺ form and the anion exchanger into the BO₃³⁻ form. Potassium originates from KOH used to adjust the pH to 7.0–7.3, NH₄⁺ from the addition of ammonia and lithium from the neutron-induced nuclear reaction, $^{10}\text{B}(n, \alpha)^7\text{Li}$. The flow through both these systems is 20 m³ h⁻¹, which is about 10% of the total volume of the primary circuit water. Resins in the beds are replaced approximately once a year. Spent ion exchangers are stored in stainless steel tanks and will in the future be solidified for final disposal, possibly by direct incorporation in concrete.

Deep beds containing ion exchange resins in the bead form remove both ions and particles. Removal of ^{137}Cs is practically 100%. In eight Swedish BWR plants the removal efficiency for corrosion prod-

ucts has been found to be about 95% for copper and chromium, 85–95% for cobalt and zinc and 80–90% for iron and nickel.

Polishing of Steam Condensate

In BWRs, the primary circuit water is boiling and the steam goes directly to turbines, after which it is condensed back to water and recirculated in the reactor vessel. This condensate is cleaned with ion exchanger filters. At the Olkiluoto NPP the condensate (60°C) goes through seven parallel filter units. Each unit has 25 L polypropylene pre-coat filter elements, which are coated with powdered anion and cation resins in a ratio of 1 : 2 or 1 : 3. The amount of resins in the seven units totals about 150–200 kg. Ion exchangers on the filters are replaced every 40–60 days. The primary purpose of the clean-up system is to remove ionic and particulate contaminants from the condensate. The removal efficiency for ionic radioactive species is higher than 90% and for particulate corrosion products 40–95%. In cases of leakages in the condenser, the clean-up system should also be able to remove ionic contaminants from the condenser coolant, which, in the case of the Olkiluoto NPP, is sea water.

In PWRs, condensate polishing is not important in removing radioactive contaminants because the condenser is located in the secondary circuit. The need for radioactivity removal from the condensate arises only if there is a leakage in the steam generator. The purpose of the condensate polishing, therefore, is usually the removal of corrosion products and corrosive agents.

Purification of Spent Fuel Storage Pond Water

Spent nuclear fuel is stored in water-filled ponds for several years after removal from the reactor. The water becomes contaminated because there is a large amount of particulate matter on the surface of fuel elements and because there are leakages of fission products through the fuel element cladding. In order to remove these contaminants, as well as the corrosive agents, the pond water is circulated through ion exchange filters. At the Olkiluoto NPP, fuel pond waters are purified with pre-coat filters in which the filter elements have been coated with H^+ - and OH^- -form resins in the ratio of 3 : 1. The flow through the filters is $180\text{ m}^3\text{ h}^{-1}$. At the Loviisa NPP there are separate 2 m^3 cation and anion exchanger beds in H^+ and BO_3^{3-} forms, respectively, and the particle removal is accomplished with mechanical filters. The flow rate is $18\text{--}40\text{ m}^3\text{ h}^{-1}$.

Treatment of Radioactive Waste Solutions

Low- and medium-activity waste solutions, originating from various sources such as leakages from

primary circuit, drainage waters, decontamination solutions, laundries, etc., are usually concentrated by evaporation or solidified by precipitation or by ion exchange. The most important radionuclides in power plant waste solutions are usually ^{137}Cs and ^{60}Co . At the Olkiluoto NPP most waste solutions are solidified with ordinary ion exchange resins, and both deep beds and pre-coat filters are used. After removal of radioactivity by the resins, they are dried and mixed with bitumen in the ratio of 1 : 1, and finally cast into 200 L steel drums for final disposal.

The number of novel ion exchange applications in nuclear waste management has been increasing since the late 1980s. Evaporators have been replaced by ion exchange processes and more selective ion exchangers, especially zeolites, have been introduced into separation processes. There are two main advantages in using selective ion exchange materials: firstly, reduction in final waste volumes and thus in waste disposal costs; and, secondly, reduction in environmental discharges of radioactivity. In 1986–87 Duratek Co., for example, replaced evaporators at four PWRs in the USA with ion exchange units. In these units there are five 0.85 m^3 columns in series, packed with both conventional ion exchange resins and novel ion-selective materials. The burial volume reduction, obtained with these new systems, was 94–95% and costs decreased by 33–77%. The decontamination factors, however, were only moderate being 15–20 for caesium and 4–24 for cobalt. Decontamination factor (DF) is the ratio of initial solution activity to the activity of purified solution.

At the Catawba NPP, USA, organic resins were replaced in 1987 with a natural zeolite, clinoptilolite, in the treatment of low-level nuclear waste solutions. Clinoptilolite is an aluminium silicate mineral with the ideal composition of $(\text{Na}_2\text{K}_2)\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 10\text{SiO}_2 \cdot 8\text{H}_2\text{O}$, where sodium and potassium ions are exchangeable for caesium. In column operation with 0.7 m^3 beds, caesium breakthrough typically occurs at 6000 bed volumes, compared to 1300 bed volumes obtained earlier with organic resins. In the laboratory studies, which were made to select the best ion exchange material, it was found that chabazite and mordenite zeolites worked as effectively as clinoptilolite, but the latter was chosen because of its lower price. Zeolites are used also at other NPPs in the USA for the removal of caesium for low-activity waste solutions.

Zeolites were also used at the Three Mile Island NPP, USA, for the decontamination of highly active waste solution from the reactor accident in 1979. 2780 m^3 of waste solution, which had ^{137}Cs and ^{90}Sr as major radioactive contaminants, were processed with an ion exchange system having four 230 L

zeolite columns in series. The columns contained two zeolites, IONSIV IE-96 and IONSIV A-51 (UOP, USA), in the ratio of 3 : 2. IE-96 has a Si/Al ratio of 2 : 3, typical for zeolite Y, and was selected because of its selectivity to caesium; A-51 has a Si/Al ratio of 1 : 1, typical for zeolites A and X, and was found to be selective for strontium. In total 10 columns containing some 60 000 Ci of caesium and strontium, were obtained from the process. The zeolites were vitrified for final disposal by adding glass-forming agents and heating at 1050°C.

In the 1990s a new, extremely selective ion exchange material for caesium separation, a transition metal hexacyanoferrate product CsTreat® (Selion, Finland), has been used at nuclear power plants. The general formula of transition metal hexacyanoferrates is $A_x[M_2Fe(CN)_6] \cdot xH_2O$, where M is a transition metal, such as cobalt, nickel or zinc, and A is the exchangeable alkali metal (Na, K). Transition metal hexacyanoferrates have long been known as superior ion exchangers for caesium compared with organic resins and zeolites. The first application, however, using granular hexacyanoferrate in packed bed columns, was commenced in 1992 at the Loviisa NPP, Finland. The solutions treated are evaporator concentrates, which are highly alkaline and contain very high concentrations of inactive salts, typically sodium at 3 mol L⁻¹ and potassium at one-tenth of this value. These types of solutions would cause instant breakthrough of caesium from zeolite and organic resin beds. In the first full-scale run, one 8 L hexacyanoferrate column processed 182 m³ of waste solution with a decontamination factor of 2000. Thus the volume reduction obtained by this method was 23 000. Another application of CsTreat® is the removal of caesium from dilute salt solutions (Na 100–300 ppm, K 10–20 ppm, Ca 20–60 ppm) at Callaway NPP, USA, where it replaces an evaporator system. Since there are also other waste components to be removed the system contains, in addition to a 250 L CsTreat® bed, mechanical filters, a charcoal bed and a mixed resin bed. During the first eight months the system purified 1800 m³ (7000 bed volumes) of waste effluents. The ¹³⁷Cs level in the purified solution was most of the time below the detection limit or at least below the target limit of 2 Bq L⁻¹ (5×10^{-7} µCi mL⁻¹). The expected additional lifetime of the bed is as long as 7 years.

Successes comparable to those with cesium removal have not been obtained for cobalt. Most waste solutions containing ⁶⁰Co are neutral or alkaline and usually the cobalt does not exist only in the divalent cation form. The forms in which the radioactive cobalt does exist are not exactly known but it is thought

to be present, in addition to divalent cations, as colloids, hydrolysis products and complexes. The most widely and successfully used separation materials for cobalt have been activated carbons. The uptake mechanism is rather complex and varies from product to product but probably activated carbons act as multifunctional materials, including ion exchange, complexation and adsorption.

For the more effective separation of activation/corrosion products ⁶⁰Co and ⁶⁵Zn, a new organic resin Diphonix has been employed at Millstone NPP, USA, since 1995. Diphonix (Eichrom Industries, USA) has a poly(styrene-divinylbenzene) matrix but the functional groups are chelating diphosphonic groups ($-(PO_3)_2^{2-}$). In addition there are sulfonic acid groups which improve the kinetics of ion exchange. In tests prior to installation of full-scale Diphonix beds at Millstone, decontamination factors (DF) for ⁶⁰Co and ⁶⁵Zn were 100 and below when a Diphonix was used alone. Combining an anion exchange resin bed with Diphonix bed increased the DF up to 1000. The processing capacity of the Diphonix bed for ⁶⁰Co and ⁶⁵Zn was at least 6000 bed volumes, which is at least 3–10 times higher than that obtained with the previously used ordinary mixed bed system.

Ion Exchange Processes at Nuclear Fuel Reprocessing Plants

Spent nuclear fuel contains about 96% uranium, 3% fission products, 1% plutonium and less than 0.1% other transuranium elements. In reprocessing the fissile material, uranium and plutonium are separated from fission products and from other actinides and recycled for the production of nuclear fuel for reactors. The main separation process utilizes solvent extraction and most reprocessing plants use the Purex process. As the first organic ion exchange resins became available in the 1940s, reprocessing schemes using ion exchange in the main process were designed but were never used due to the poor decontamination factors achieved. Today, ion exchange is used at reprocessing plants only in the secondary waste effluent treatment and separation streams.

Separation Processes

The most important use of ion exchange in the separation processes is the purification of plutonium solutions, which can be carried out with both cation and anion exchangers. Anion exchange processes, however, yield better decontamination from impurities. At high nitric acid concentrations plutonium forms the hexanitro complex anion $Pu(NO_3)_6^{2-}$, which can

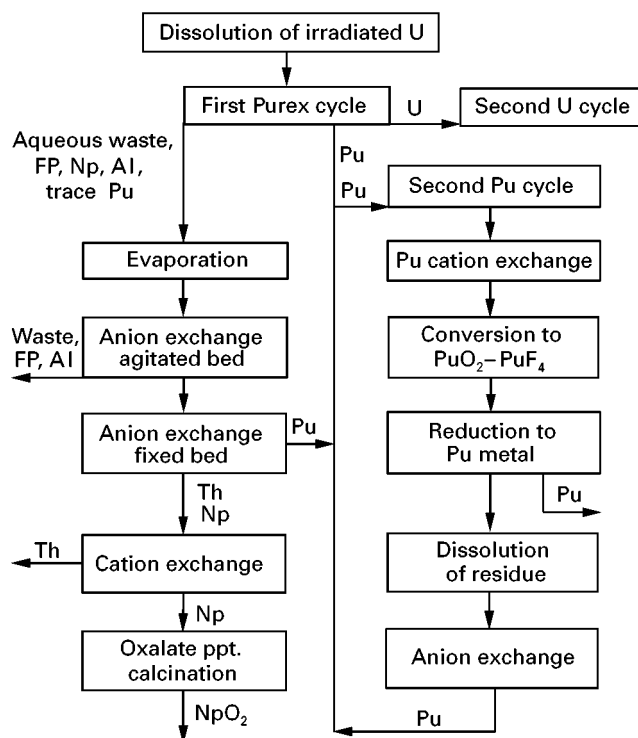

Figure 2 Ion exchange processes in the reprocessing of spent uranium fuel at the Savannah River Plant, USA.

be sorbed on an anion exchange resin in the following way:

The optimum nitric acid concentration is 7 mol L⁻¹. Plutonium can be eluted from the resin with diluted nitric acid (0.35 mol L⁻¹) as the hexanitro complex is destroyed. The decontamination factor for all other elements but neptunium is very good. Plutonium can be purified from neptunium by eluting with 5.5 mol L⁻¹ HNO₃ containing iron(II) sulfamate and hydrazine, instead of 0.35 mol L⁻¹ HNO₃. Plutonium is reduced to Pu(III) and elutes from the column, while Np(IV) remains.

Anion and cation exchange processes can also be used for the separation of plutonium and neptunium from the high-level waste solutions of the Purex process (Figure 2). Plutonium is recycled to the Purex process and neptunium turned into NpO₂ to be used as irradiation targets.

Treatment of Radioactive Waste Solutions

The high activity waste effluents from civilian reprocessing plants are usually calcined and vitrified for final disposal. In the 1970s and 1980s studies

were carried out on the use of inorganic ion exchangers, zeolites and sodium titanate, in the solidification of highly active waste solutions but no such processes are currently employed. In the late 1980s a zeolite IONSIV IE-96 was, however, used at West Valley reprocessing plant in New York for the removal of ¹³⁷Cs in 2100 m³ of highly active neutralized Purex-process-derived waste solution. In total about 30 columns of 1.7 m³ volume were obtained, the volume reduction thus being about 40-fold. The decontamination factor was higher than 10 000. Zeolite, together with the sludge from the tank bottom, was vitrified for final disposal.

Starting in 1997, the Japan Atomic Energy Research Institute (JAERI) inaugurated the first use at reprocessing plants of highly selective inorganic ion exchange materials in packed bed columns for the removal of ¹³⁷Cs and ⁹⁰Sr from reprocessing waste effluents and the process has worked successfully. In this pilot-scale process 2 L columns are packed in the ratio of 1 : 1 with the hexacyanoferrate product CsTreat® and a sodium titanate product SrTreat® (Selion, Finland) which is a highly selective ion exchanger for strontium in alkaline media and efficiently takes up other multivalent radionuclides. In laboratory tests with JAERI simulant (pH 10, 2.4 mol L⁻¹ NaNO₃) the average decontamination factor of SrTreat® for strontium was 8400 at 1500

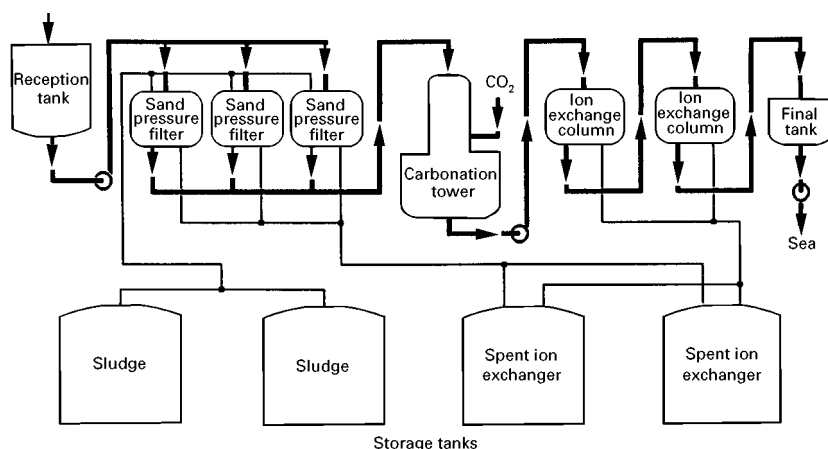

Figure 3 Simplified process flow diagram for the Site Ion Exchange Effluent Plant (SIXEP) at Sellafield, UK.

bed volumes. In other tests SrTreat® has also been shown to take up strontium most efficiently from military waste effluents (see below) which represent the most severe conditions where ion exchange can be considered for use in waste management.

In 1985 the Site Ion Exchange Effluent Plant (SIXEP), using the natural clinoptilolite zeolite for the removal of caesium and strontium from spent fuel pond waters, was put into operation at the BNFL Sellafield reprocessing plant in the UK. Spent fuel to be reprocessed is stored in water-filled storage ponds and some 3600 m³ of the pond water have to be purged every day to keep the radiation in the ponds at an acceptable level. From this water, containing radioactive caesium and strontium, as well as activated corrosion products, particulate matter is first removed in sand filters and the pH is lowered with CO₂ from 11.5 to 8.0 to avoid the dissolution of the zeolite exchanger. Finally, the solution is passed through two beds in series, both columns filled with 10 m³ of zeolite (Figure 3). The plant annually processes 700 000 m³ of pond water, containing 17 000 Ci activity. The decontamination factors are typically 2000 and 500 for caesium and strontium, respectively, and the plant treats 20 000 bed volumes per change of zeolite. The yearly consumption of zeolite is 40 m³.

At the Sellafield plant there is also another major waste treatment process utilizing ion exchange, the Enhanced Actinide Removal Plant (EARP), commissioned in 1994. From the mainly medium activity solutions the alpha nuclides are removed by increasing the pH to 10–11, which causes the precipitation of iron hydroxides and subsequently practically all actinides. Solid/liquid separation is accomplished with cross-flow filtration through ceramic mem-

branes. The removal of caesium is carried out by addition of preformed nickel hexacyanoferrate sludge, which removes caesium by ion exchange and yields moderate decontamination factors of 10–50. This way of using selective ion exchangers, called seeded ultrafiltration, is well suited to combination with coprecipitation with ferric floc, but in general it is much less efficient when compared with the use of exchangers in packed bed columns, taking into account both decontamination factors and processing capacities.

Decontamination of Military Waste Effluents

Especially in the USA and Russia there are huge amounts of highly active waste effluents, originating from nuclear weapons programmes, stored in tanks, a large number of which are leaking or expected to leak. The US Department of Energy has launched a long-term programme to treat and solidify tank wastes, which consist of salt cakes and sludges in the tank bottoms and supernatants above. In total, there are 300 000 m³ of tank wastes, especially at the Hanford and Savannah River sites. Supernatants are highly alkaline, their pH being above 14, and the concentration of salts is very high, for example that of sodium is as high as 7 mol L⁻¹. The objective is to separate the main soluble radionuclides, ¹³⁷Cs, ⁹⁰Sr and ⁹⁹Tc, to minimize the volume of highly active waste to be disposed of. It is expected that ion exchange will be the main process used to do this. The extreme conditions in the solutions impose the most stringent requirements on the exchangers, considering both selectivity and chemical stability. Development of materials for tank waste remediation is discussed in the next section.

New Developments in Ion Exchange Materials

In the development of nuclear grade ion exchange resins, used in primary coolant and condensate purification, the main effort has been to decrease the fractions of leachables, both resin fragments and ionic leachables. In the development of ion exchange materials for waste treatment, where ordinary organic resins are mostly ruled out due to their low selectivities, the most important objectives have been:

1. To obtain highly selective exchanger materials for certain radionuclides.
2. To obtain ion exchange materials stable and capable of ion exchange in highly acidic or highly alkaline media.
3. To obtain ion exchangers in granular or bead forms suitable for packed bed column operations.

The highest selectivities have been found with inorganic ion exchangers. The biggest effort in developing novel ion exchange materials for radionuclide removal has been devoted to caesium-selective exchangers. In the mid-1980s zeolites were the first generation of caesium-selective exchangers. Thereafter, a wide variety of exchangers have been studied for this purpose; transition metal hexacyanoferrates, such as CsTreat[®] discussed earlier, have the highest selectivity for caesium (Table 1).

Utilization of zeolites and CsTreat[®] has been discussed above. Crystalline silicotitanate CST (UOP, USA) has been developed during the 1990s by optimizing the Si/Ti ratio in the exchanger and using additional metals ions, such as niobium, in the structure of the layered material. The most important possible utilization of CST is the remediation of US tank wastes, since CST has been reported to be stable in their extremely alkaline environments and to be efficient for the uptake of both caesium and strontium from the supernatants. Many other inorganic ion exchangers, especially mixed oxides, have been developed and commercialized by Allied Signal, USA.

Table 1 Selectivity coefficients of Cs/Na exchange in commercial Cs-selective ion exchange materials

<i>Ion exchanger</i>	<i>Selectivity coefficient</i>
Sulfonic acid resin	< 10
Mordenite (zeolite)	450
Resorcinol formaldehyde resin (SRL)	11 400
Silicotitanate (CST)	18 000
Hexacyanoferrate (CsTreat [®])	1 500 000

A wide variety of chelating resins have been developed and tested for the separation of transition metal ions from solution. Of these, only a few resins, particularly iminodiacetic acid [R-N-(CH₂-COOH)₂] and aminophosphonate (R-NH-CH₂-PO₃H₂), are manufactured commercially but no applications in the nuclear industry have been reported. The only exception is the Diphonix resin discussed above. The company manufacturing Diphonix, Eichrom Industries, also produces several other radionuclide-selective resins. These 'extraction chromatographic resins' are mainly based on the incorporation of complexing agents, known to be efficient in solvent extraction processes, into the solid resin matrix so that they can be used in packed bed columns. An example of these resins is the SrResin which contains a strontium-selective crown ether in the resin matrix. The high prices of these chromatographic resins are likely to limit their use to analytical applications.

⁹⁹Tc is an important radionuclide in high activity waste effluents due to its very long half-life. Technetium is mainly present as a pertechnetate anion TcO₄⁻ and is difficult to remove. No really selective ion exchanger has so far been developed for the effective separation of technetium from waste effluents. However, the capability of ordinary anion resins to take up technetium has been improved by modifying the side chains in the functional groups -R-N(C_xH_y)₃⁺ of strongly basic anion exchange resins. For example, compared with a commercial resin containing ethyl groups as C₂H₅, a test resin containing both hexyl and propyl groups removed TcO₄⁻ from ground water much more efficiently, the processing capacity being more than × 30 higher.

NUCLEIC ACIDS

Centrifugation

A. Marziali, University of British Columbia, Vancouver, Canada

Copyright © 2000 Academic Press

Introduction

Centrifugation has been applied to nucleic acid isolation and purification through numerous protocols which, at some level, contain elements of one or more of three basic techniques: isopycnic or density equilibrium separation, phenol-chloroform extraction, and differential precipitation. Even if we consider only the protocols that are in current use, numerous variations on these appear in the literature. These variations result from the intended use of the product, the required purity from specific contaminants, the cost and throughput goals of the technique, and often the author's personal preferences. This article will make no attempt to cover all variations but will instead illustrate by example the basic forms of centrifuge-based techniques for nucleic acid separation as they are presently used. A rough guide to these three basic techniques and their applications is contained in Table 1. Each of these will subsequently be described separately.

Recent demands imposed on nucleic acid purifications by large scale DNA sequencing operations have led to the development, and increased use of filtration-based purification methods for high throughput separations. Though the cost of the filter membranes required for these separations is much higher than the cost of centrifugation, the throughput and ease of automation of the membrane based methods make them preferable in many situations. Recent developments in automation of centrifugation, discussed in the last section of this article, may reverse this trend.

Isopycnic Separations

General Principle

Isopycnic separations rely on the balancing of the buoyant and centrifugal forces acting on a submerged sample during centrifugation. When a sample of density ρ_s and effective volume V is placed in a medium of density ρ_m in the presence of a centrifugal field a , the sample feels an upward buoyant force $F_b = \rho_m Va$, and an opposing centrifugal force $F_c = \rho_s Va$. Consequently, the sample will move 'up' toward the rotation axis if $\rho_s < \rho_m$ and 'down' if $\rho_s > \rho_m$. This motion terminates when the sample reaches the boundary of the medium or when it enters a region of the medium where $\rho_s = \rho_m$. Based on this principle, if a sample container is filled with a medium whose density increases gradually in the downward direction, a sample injected in this medium will migrate to the region of the medium that matches the sample density (provided such a region exists). This location is known as the isopycnic point of the sample.

Samples may therefore be separated based on their densities provided a medium is found that can be formed into a density gradient and whose density range includes that of the sample. One of the criteria in the selection of separation media for a specific sample is to ensure that this condition is met.

After a substantial migration period (often over a day), the sample fractions of different densities can be observed as bands within the medium. Extraction of these bands is performed by puncturing the centrifuge tube with a hypodermic needle and withdrawing the desired band. The resolution provided by this method is a function of the separation medium and the relative density difference in the fractions to be separated.

In the case of nucleic acids, RNA and DNA exhibit very different densities in aqueous solutions and therefore can be separated. Cesium salt solutions are typically used as the separation medium since in

THERMALLY-COUPLED COLUMNS: DISTILLATION

R. Smith, Centre for Process Integration, UMIST, Manchester, UK

Copyright © 2000 Academic Press

Introduction

A considerable amount of energy is used in distillation operations. Energy integration has proven to be successful in reducing energy costs for conventional distillation arrangements. However, the scope for energy integration of conventional distillation columns into an overall process is often limited. Also, practical constraints often prevent integration of distillation columns with the rest of the process.

If the column cannot be integrated with the rest of the process or, if the potential for heat integration is limited by the heat flows in the background process, then we must turn our attention back to the distillation operation itself and look at unconventional arrangements.

Figure 1 shows two conventional arrangements for the separation of a three-component mixture. The sequence shown in Figure 1A is the so-called direct sequence, in which the lightest component is taken overhead in each column. The indirect sequence shown in Figure 1B takes the heaviest component as bottom product in each column.

One of the most significant unconventional arrangements involves thermal coupling. Figure 2 shows a number of unconventional arrangements that use thermal coupling. In thermal coupling part of the heat transfer necessary for the separation is provided by direct contact via material flows. Figure 2A shows a side-rectifier arrangement and Figure 2B a side-stripper arrangement. Arrangements similar to that in Figure 2B are widely used in petroleum refining. The fully thermally coupled arrangement in Figure 2C (sometimes known as the Petlyuk column) has been known for over 50 years. Various studies have shown that thermally coupled arrangements can

save up to 30% of energy costs when compared with conventional arrangements.

Simple Versus Complex Columns

Consider first the design of distillation systems comprising only simple columns. These simple columns employ:

- one feed split into two products;
- key components which are adjacent in volatility;
- a reboiler and a condenser.

For a three-component mixture in which simple columns are employed, the decision is between the two sequences illustrated in Figure 1.

Consider the first characteristic of simple columns, which involves a single feed being split into two products. As a first option to two simple columns, the possibilities shown in Figure 3 can be considered, in which three products are taken from one column. The designs can be both feasible and cost-effective when compared with simple arrangements, but only for certain conditions. If the feed is dominated by the middle product (typically more than 50% of the feed) and the heaviest product is present in small quantities (typically less than 5%) then the arrangement shown in Figure 3A can be an attractive option. If a pure middle product is required, then it is usually only possible if there is a large volatility difference between components B and C, with the middle product taken as a vapour to assist the separation. The heavy product must find its way down the column past the side-stream. Unless the heavy product has a small flow and the middle product a high flow, a reasonably pure middle product cannot be achieved.

If the feed is dominated by the middle product (typically more than 50%) and the lightest product is present in small quantities (typically less than 5%), then the arrangement shown in Figure 3B can be an attractive option. This time the light product must find its way up the column past the side-stream. If

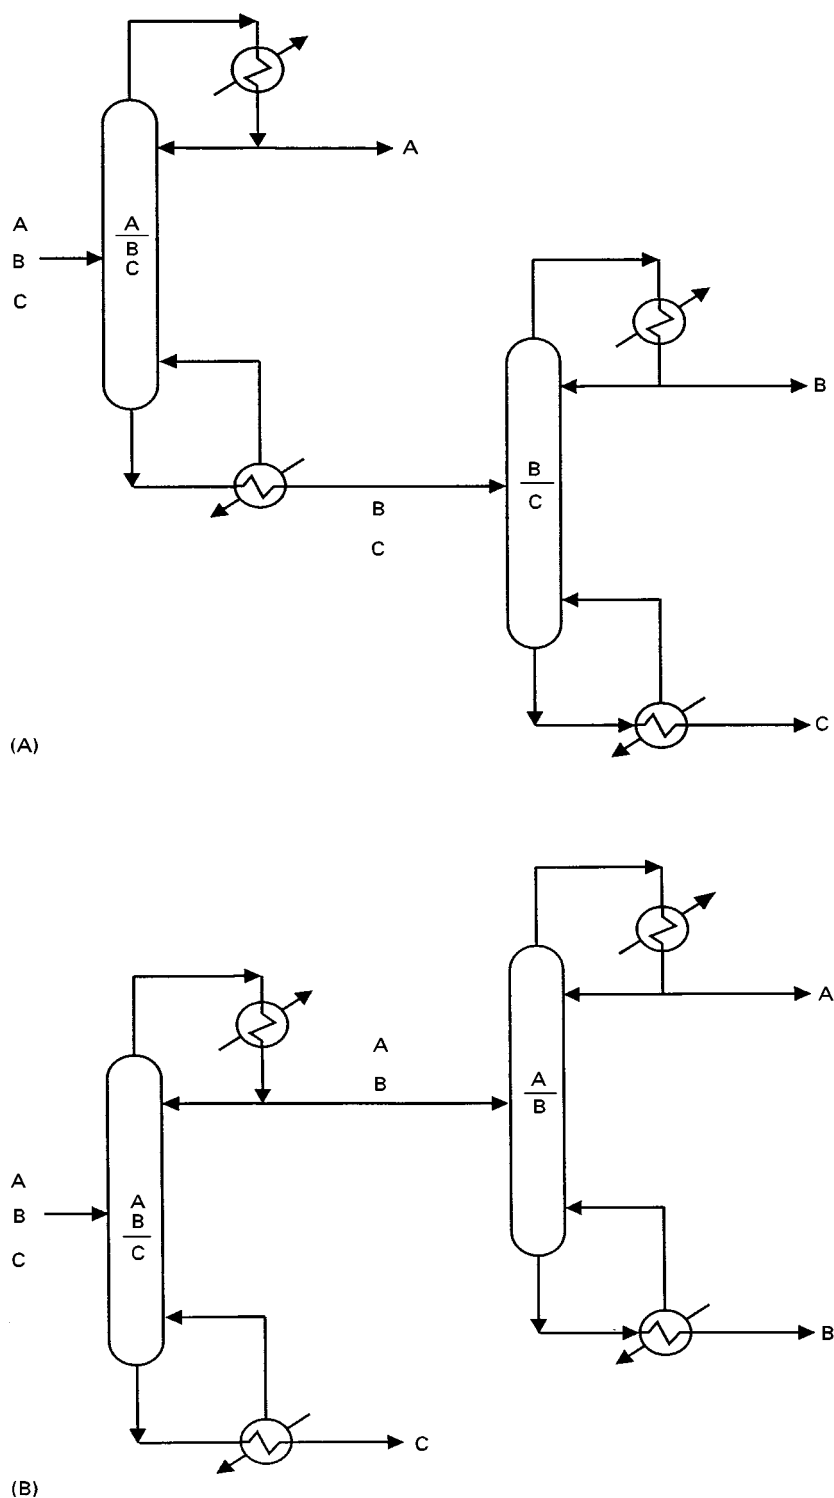

Figure 1 The (A) direct and (B) indirect sequences of simple distillation columns for a three-component separation. (Reproduced with permission from Triantafyllou and Smith (1992) *Transactions of the Institution of Chemical Engineers, Part A* 70: 1992.)

a pure middle product is required, then it is usually only possible if there is a large volatility difference between components A and B, with the middle product taken as a liquid to assist the separation.

In summary, single-column side-stream arrangements can be attractive when the middle product is in excess and one of the other components is present in only minor quantities. Thus, the side-stream column

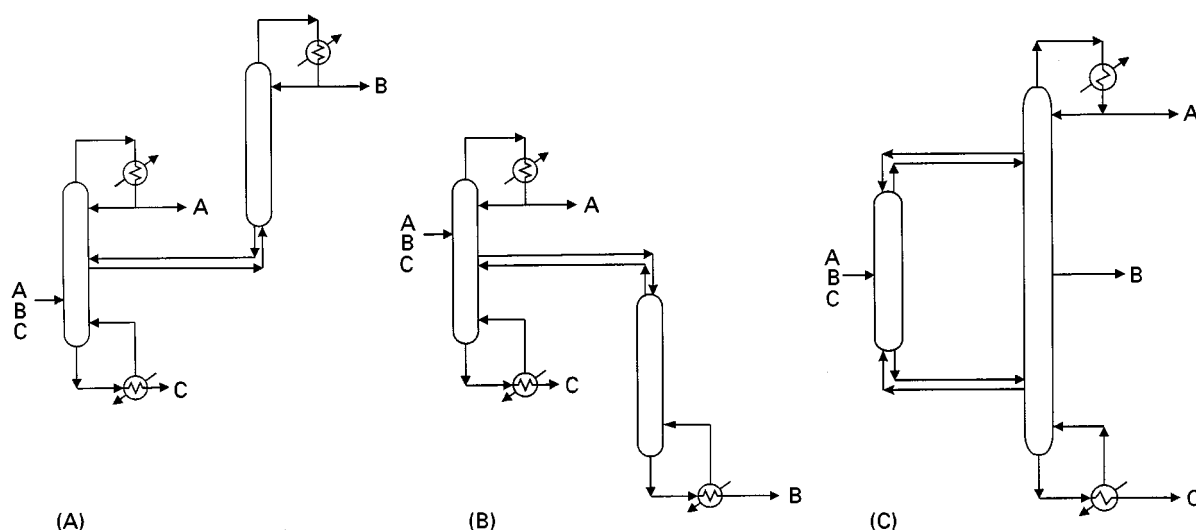

Figure 2 Thermally coupled columns. (A) Side-rectifier; (B) side-stripper; (C) fully thermally coupled column. (Reproduced with permission from Triantafyllou and Smith (1992) *Transactions of the Institution of Chemical Engineers, Part A* 70, 118.)

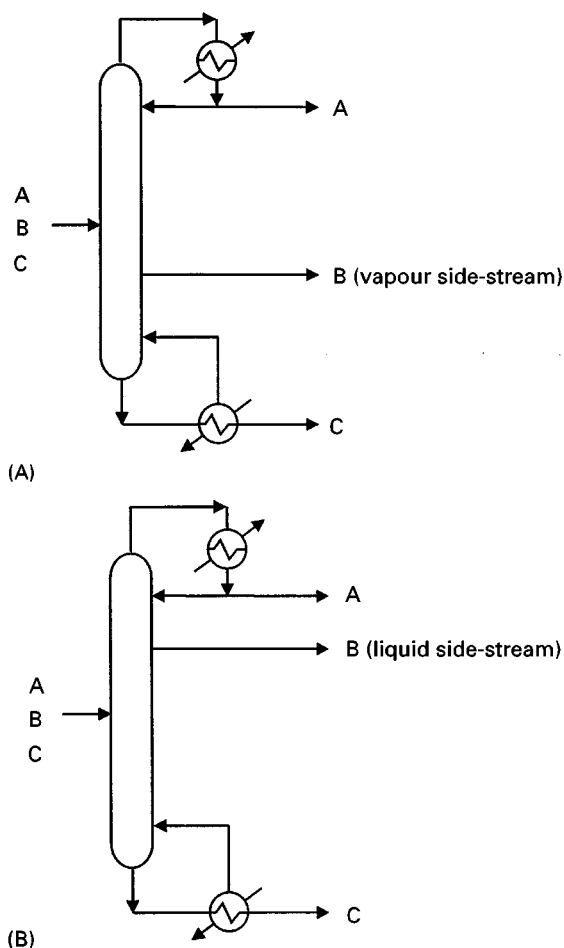

Figure 3 Distillation columns with three products. (A) More than 50% middle component and less than 5% heaviest component; (B) more than 50% middle component and less than 5% lightest component. (From Smith and Linnhoff (1988) *Chemical Engineering Research and Design*, 66, 195, reproduced with permission from the Institution of Chemical Engineers.)

only applies to special feed compositions. More generally applicable arrangements are possible by relaxing the restriction that separations must be between adjacent key components.

Consider a three-product separation as shown in Figure 4A in which the lightest and heaviest components are chosen to be the key separation in the first column. In such a case, two further columns are required to produce pure products. However, note that the bottoms and overheads of the second and third columns in Figure 4A are both pure B. Hence the second and third columns could simply be connected and product B taken as a side-stream, as shown in Figure 4B. The arrangement in Figure 4B is known as a prefractionator arrangement. Note that the first column in Figure 4B, the prefractionator, has a partial condenser to reduce the overall energy consumption. The prefractionator arrangement in Figure 4B typically requires 30% less energy than conventional arrangements for the same separation duty. The extent of the energy saving depends on the feed composition and the relative volatility of the components being separated. The energy saving results from the fact that the prefractionator arrangement is thermodynamically more efficient than a simple arrangement.

To understand why this is the case, consider the sequence of simple columns shown in Figure 5. In the direct sequence shown in Figure 5, the composition of component B in the first column increases below the feed as the more volatile component A decreases. However, moving further down the column, the composition of B decreases again as the composition of the less volatile component C increases. Thus, the composition of B reaches a peak, only to be remixed.

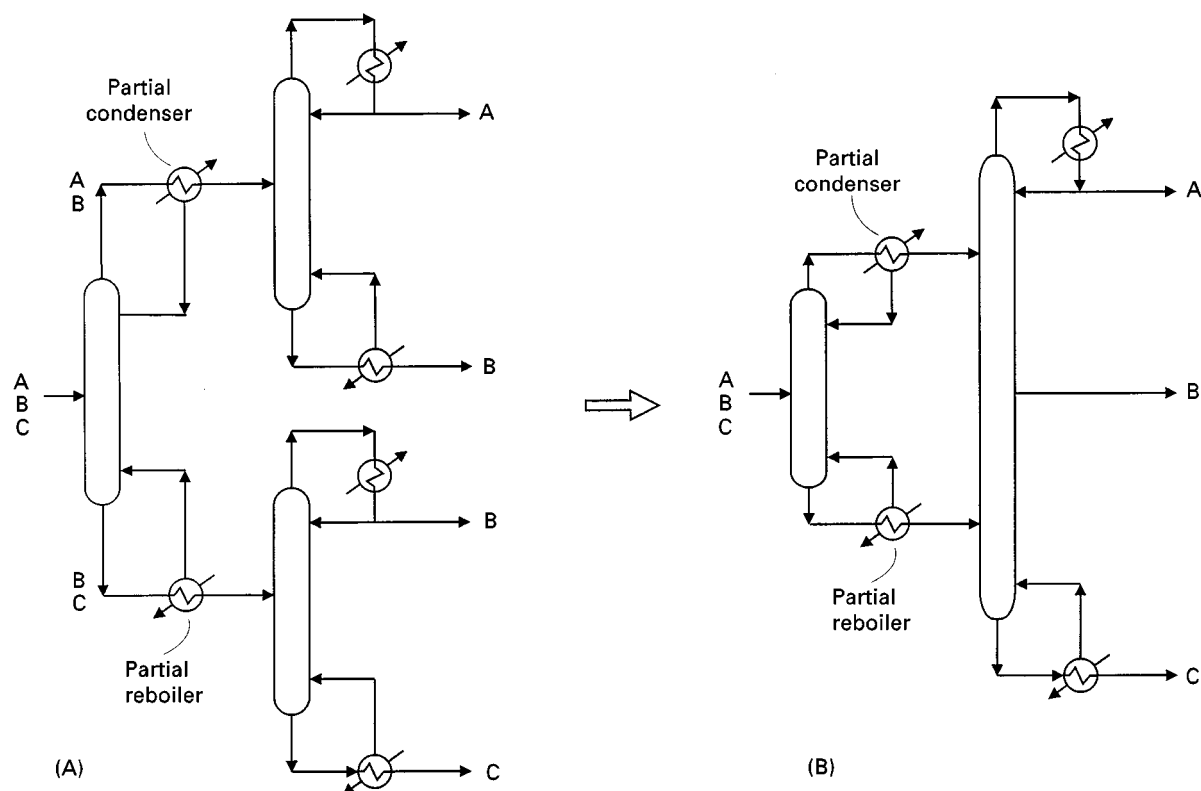

Figure 4 Choosing nonadjacent keys leads to the prefractionator arrangement. (A) Sequence for three product separation using nonadjacent keys; (B) prefractionator arrangement. (Reproduced with permission from Smith (1995) *Chemical Process Design*, McGraw-Hill.)

Similarly, with the first column in the indirect sequence, the composition of B first increases above the feed and reaches a maximum only to decrease as

the more volatile component A increases. Again, the composition of B reaches a peak, only to be removed.

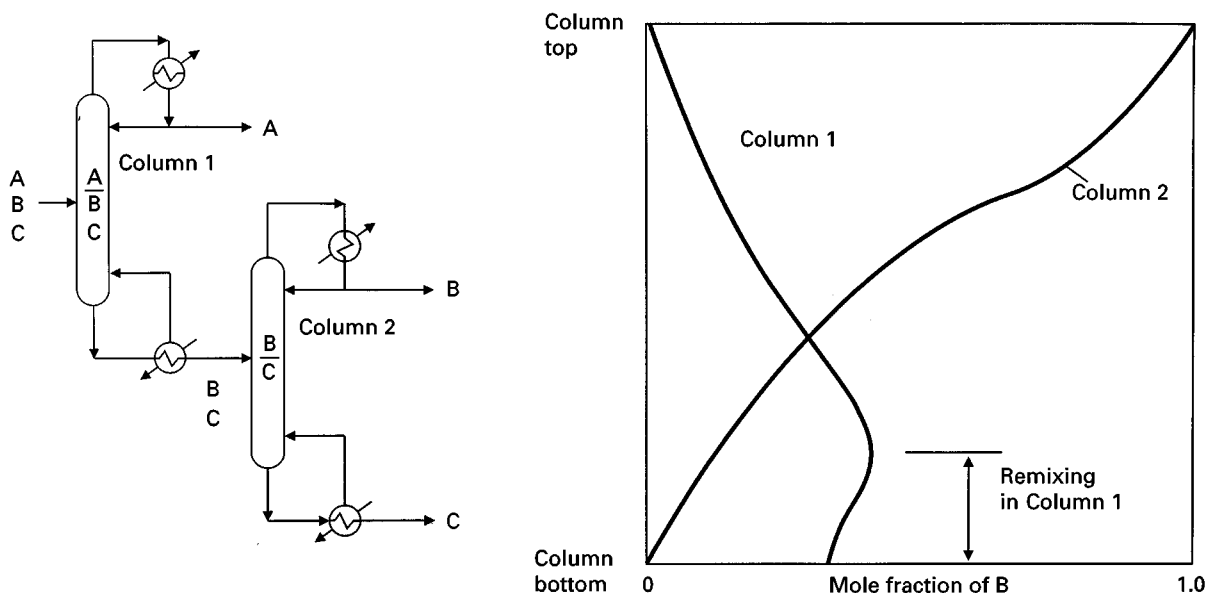

Figure 5 Composition profiles for the middle product in the columns of the direct sequence show remixing effects. (From Triantafyllou and Smith (1992) *Transactions of the Institution of Chemical Engineers, Part A* 70, 118, reproduced by permission of the Institution of Chemical Engineers.)

Figure 6 Composition profiles for the middle product in the prefractionator arrangement show that there are no remixing effects. (From Triantafyllou and Smith (1992) *Transactions of the Institution of Chemical Engineers, Part A* 70, 118, reproduced by permission of the Institution of Chemical Engineers.)

This remixing which occurs in both sequences of simple distillation columns is a source of inefficiency in the separation. By contrast, consider the prefractionator arrangement shown in **Figure 6**. In the prefractionator, a crude split is performed so that component B is distributed between the top and bottom of the column. The upper section of the prefractionator separates AB from C, whilst the lower section separates BC from A. Thus, both sections remove only one component from the product of that column section and this is also true for all sections of the main column. In this way, the remixing effects which are a feature of both simple column sequences are avoided.

In addition, one other feature of the prefractionator arrangement is important in reducing mixing effects. Losses occur in distillation operations due to mismatches between the composition of the column feed and the composition on the feed tray. Because the prefractionator distributes B between top and bottom, this allows greater freedom to match the feed composition with one of the trays in the column to reduce mixing losses at the feed tray.

Distillation Using Thermal Coupling

Rather than each column having a reboiler and condenser, it is possible to use material flows to provide some of the necessary heat transfer by direct-contact thermal coupling.

First consider thermal coupling of the simple sequences from **Figure 1**. **Figure 7A** shows a thermally coupled direct sequence in which the reboiler of the first column is replaced by thermal coupling. Liquid from the bottom of the first column is transferred to the second as before, but now the reboiler of the second column supplies the vapour required by the first column. The four column sections marked as 1, 2, 3 and 4 in **Figure 7A** can be rearranged to form a side-rectifier arrangement, as shown in **Figure 7B**.

Similarly, **Figure 8A** shows a thermally coupled indirect sequence in which the condenser of the first column is replaced by thermal coupling. The four column sections marked as 1, 2, 3 and 4 in **Figure 8A** can again be rearranged, but this time forming a side-stripper arrangement.

Both the side-rectifier and side-stripper arrangements have been shown to reduce the energy consumption compared with simple two-column arrangements. This results from reduced mixing losses in the first (main) column. As with the first column of the simple sequence, a peak in composition occurs with the middle product, but now advantage of the peak is taken by transferring material to the side-rectifier or side-stripper.

Side-stripper arrangements are commonly used in petroleum refinery separations. **Figure 9A** shows a typical arrangement for distillation of crude oil. The main column is fed with the pre-heated crude oil feed. Products are taken from various points from the main

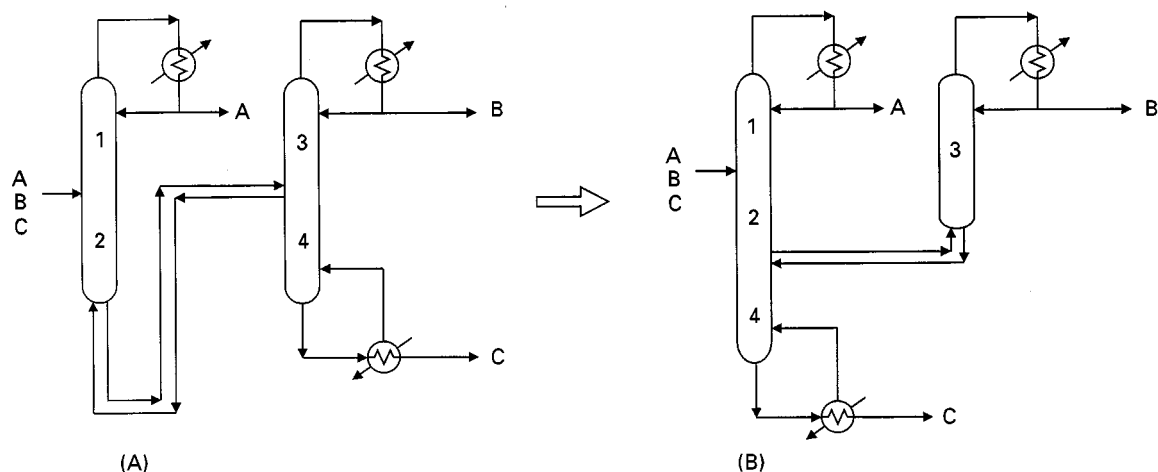

Figure 7 Thermal coupling of the direct sequence. (A) Thermally coupled direct sequence; (B) side-rectifier arrangement. (Reproduced with permission from Smith (1995) *Chemical Process Design*, McGraw-Hill.)

column via side-stripper columns. Heat is also removed at various points through the main column via pumparounds. Pumparounds take liquid from the column, cool it and return it to the column at a higher point, effectively acting as intermediate condensers. Heat to the side-strippers is supplied from either reboilers or live steam injection. The arrangement shown in Figure 9A is equivalent to a sequence of simple columns in the indirect sequence, as shown in Figure 9B.

Consider now thermal coupling of the prefractionator arrangement from Figure 10A. Figure 10B shows the equivalent thermally coupled prefractionator arrangement, sometimes known as the Petlyuk column. To make the two arrangements in Figure 10 equivalent, the thermally coupled prefractionator requires extra plates to substitute for the prefractionator condenser and reboiler.

Various studies have shown that the thermally coupled arrangement in Figure 10B requires typically 30% less energy than a conventional arrangement using simple columns. The saving depends on the feed mixture. In most cases the fully thermally coupled column in Figure 10B requires less energy than the side-rectifier and side-stripper arrangements, for the same separation. The prefractionator arrangement in Figure 10A and the thermally coupled prefractionator (Petlyuk column) in Figure 10B are similar in terms of total heating and cooling duties, but there are differences in the temperatures at which the heat is supplied and rejected.

Figure 11 shows the evolution from the prefractionator in Figure 11A to the thermally coupled prefractionator in Figure 11B. Finally, in Figure 11C, the thermally coupled prefractionator uses a single shell with a vertical baffle dividing the central section

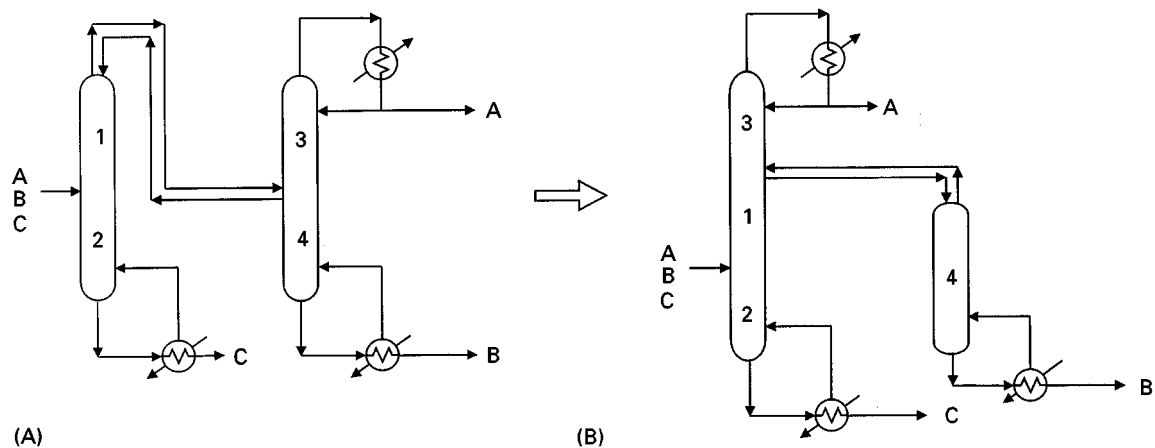

Figure 8 Thermal coupling of the indirect sequence. (A) Thermally coupled indirect sequence; (B) side-stripper arrangement. (Reproduced with permission from Smith (1995) *Chemical Process Design*, McGraw-Hill.)

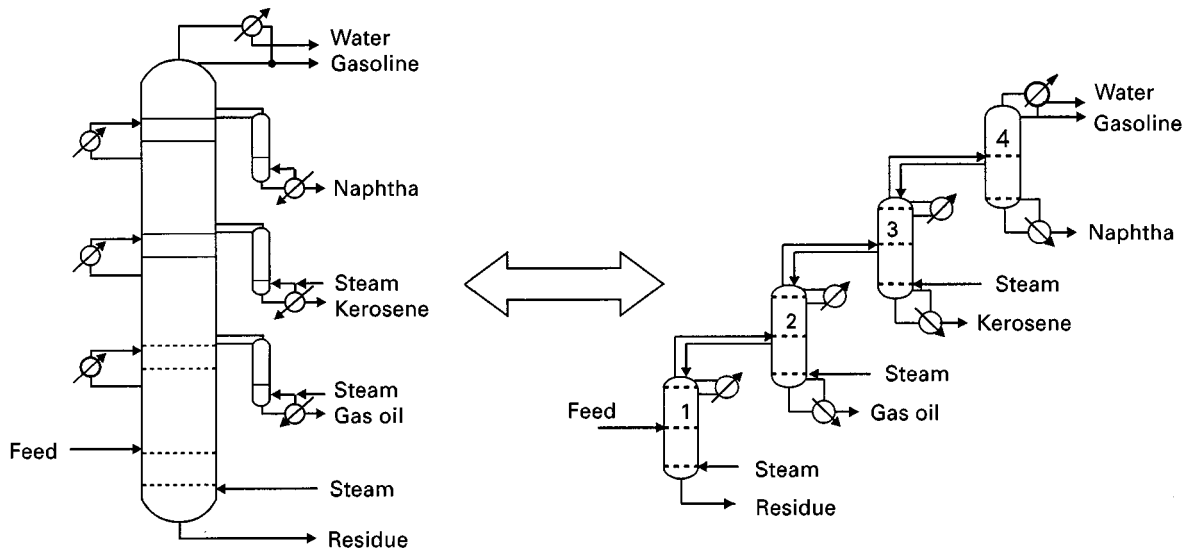

Figure 9 The typical crude oil distillation column decomposes to a sequence of simple columns in the indirect sequence.

of the shell into two parts, known as the dividing wall column or partition column. The arrangements in Figure 11 require almost the same energy consumption, which typically is 30% less than a conventional arrangement. However, in the case of the prefractionator in Figure 11A, the heat load is supplied at two points and rejected from two points. In addition, the dividing wall column in Figure 11C requires

typically 30% less capital cost than a two-column arrangement of simple columns.

Dividing Wall Columns

Dividing wall columns, as shown in Figure 11C, have been known for over 50 years and yet it is only recently that they have been applied in practice. It is

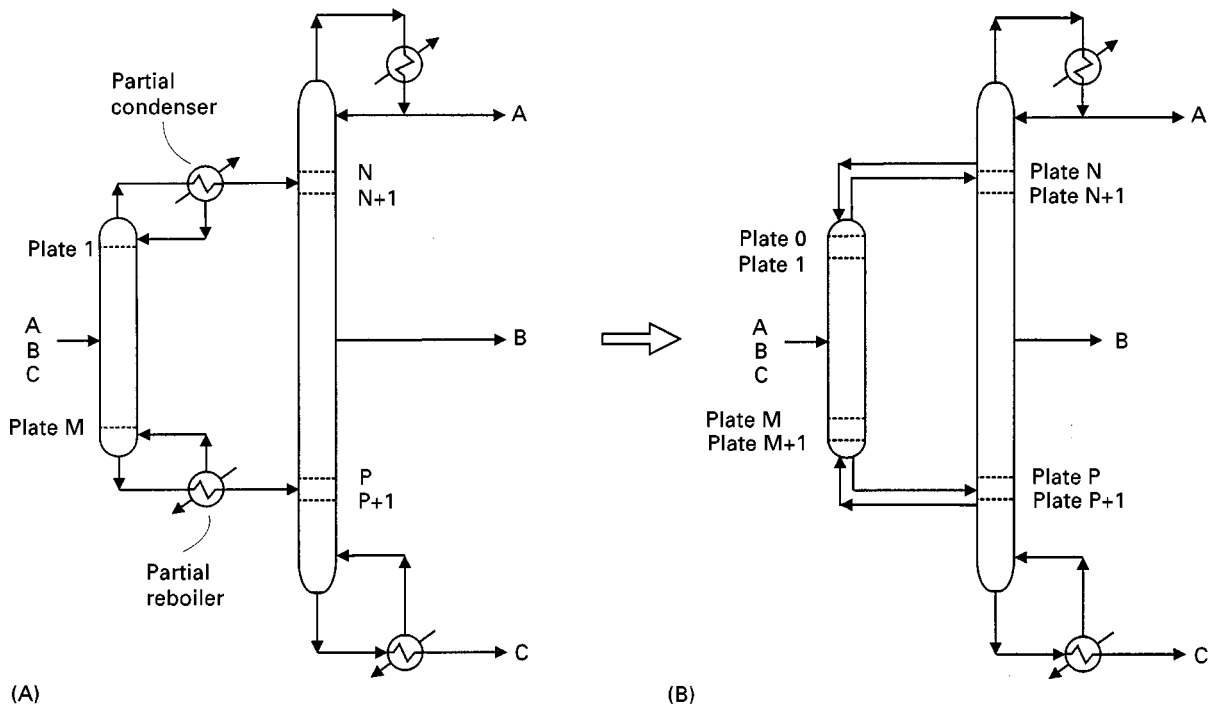

Figure 10 Thermal coupling of the prefractionator arrangement. (A) Prefractionator; (B) thermally coupled prefractionator. (Reproduced with permission from Smith (1995) *Chemical Process Design*, McGraw-Hill.)

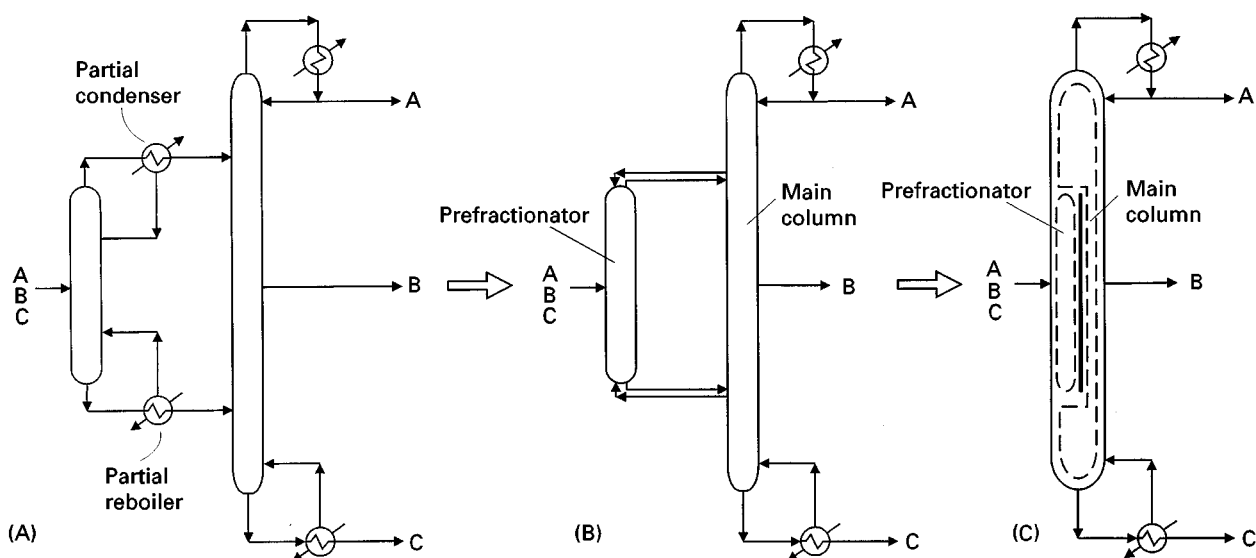

Figure 11 The thermally coupled prefractionator can be arranged in a single shell. (A) Prefractionator arrangement; (B) thermally coupled prefractionator (Petlyuk column); (C) dividing wall column. (Reproduced with permission from Smith (1995) *Chemical Process Design*, McGraw-Hill.)

true that the basic design is more problematic than a single conventional column, because there are more degrees of freedom in the design. However, methods have been developed to initialize the degrees of freedom prior to detailed simulation. Detailed simulation of the dividing wall column is carried out by modeling it as a Petlyuk arrangement, as shown in Figure 10B. Control of the column has also been

a concern. However, such concern is misplaced, as the control is straightforward, being effectively the same as control of a side-stream column. Standard temperature and composition control configuration schemes can be employed. The hardware and column internals for the dividing wall column are also standard, despite the presence of the dividing wall. However, it should be noted that the column performance

Figure 12 Thermal coupling reduces the quantity of energy required but makes temperatures more extreme.

suffers if the dividing wall is not insulated in some way. This can be done in practice by using two plates separated by a layer of insulation.

Temperature of Heat Supply and Rejection

So far the benefits of thermal coupling have been discussed in terms of the reduced energy required. Let us now consider the temperature at which the heat needs to be supplied and rejected if thermal coupling is used. It is always preferable to add the heat to the reboiler at the lowest temperature possible and to reject heat from the condenser at the highest temperature possible. In the first instance, this allows cheaper hot and cold utilities. In addition, if heat integration of the reboiler and condenser is to be considered, heat integration will also always benefit from lower reboiler temperatures and higher condenser temperatures.

Figure 12 compares a conventional and a thermally coupled arrangement in terms of temperature and enthalpy. In the conventional arrangement there is freedom to choose the pressures of the two columns independently, and thus the temperatures of the two condensers or the two reboilers can be varied independently. In the case of the thermally coupled arrangement no such freedom exists. Although the thermally coupled arrangement requires a smaller heat load than the conventional arrangement, more of the duties are at extreme levels. The smaller duties work to the benefit of utility costs and heat integration but the more extreme levels work against them.

Summary

Thermally coupled distillation columns offer considerable benefits in terms of operating costs. Side-stripper, side-rectifier and fully thermally coupled arrangements such as the Petlyuk column can save typically 30% of the energy consumption compared with sequences of simple columns. The magnitude of the saving depends on the feed composition and relative volatility of the components being separated. The dividing wall column also offers large potential savings in capital cost. Apart from the use of side-stripper arrangements in the petroleum refinery industry there has been reluctance on the part of process designers to exploit the full potential of thermal coupling. Control of thermally coupled arrangements does not present any particularly difficult problems.

THIN-LAYER CHROMATOGRAPHY – VIBRATION SPECTROSCOPY

E. Koglin, Research Center Juelich,
Juelich, Germany

Copyright © 2000 Academic Press

Introduction

The utility of vibrational spectroscopy in chemical structure elucidation of separated thin layer chromatography (TLC) spots has been recognized for many years. Although the traditional method has been infrared spectroscopy (Fourier transform infrared spectrometry (FTIR)) a number of com-

peting techniques now exist including normal Raman scattering (RS), Raman microspectroscopy (Micro-Raman), Fourier transform Raman (FT-Raman) and surface-enhanced Raman scattering (SERS). Since each type of spectra provide essential vibrational profile of analytes from the TLC plate, the different disciplines are natural partners in a general spectroscopic analysis. All methods involve the vibrational energy of the molecule and thus provide molecular and structural information about the separated sample. However, since infrared (IR) absorption, Raman scattering and SERS have different selection rules – what is frequently strong in

a Raman spectrum is weak in an IR spectrum and vice versa. For this reason, a combined IR and Raman system offers the flexibility of working with almost any sample, as well as complete vibrational information from numerous compounds.

Up to now the combination of TLC separation and IR spectroscopy has been approached in roughly two ways. The classical approach for recording IR spectra is to elute the separated TLC zones from the layer onto an IR-transparent pellet or powder (sample transfer TLC-FTIR). Numerous workers have attempted to record diffuse reflectance Fourier transform infrared (DRIFT) spectra directly on TLC plates (*in situ* TLC-FTIR). A small number of research groups have studied the applicability of near-infrared spectroscopy (NIR) in the reflectance mode as an *in situ* detection tool in TLC.

Although IR spectroscopy still yields the largest number of publications in the field of TLC vibrational analysis many serious attempts are now being made to explore the analytic potential of Raman spectroscopy in new and challenging areas of TLC spot identification. The use of Raman scattering eliminates moisture and background absorption problems which may be present in the infrared-based techniques. Therefore, a number of important advantages to this Raman technique exist: (1) most common TLC matrices can be used with little interference, (2) spectra can be taken *in situ* from wet or dry plates, (3) the well-known advantages of NIR excitation ($\lambda_{\text{ex}} = 1064 \text{ nm}$) in FT-Raman (avoidance of fluorescence and photo-induced sample damage), (4) the use of Raman microspectroscopy which allowed unambiguous placement of the laser focus on the TLC plate with spatial resolution of the order of $1 \mu\text{m}$.

One of the significant limitations of the application of Raman spectroscopy in the field of TLC chromatogram spot characterization is the lack of sensitivity. An important step forward was made by SERS. Raman scattering intensities from adsorbed substances on nano-metal particles (Ag, Au, Cu) are increased by a factor of 10^5 – 10^6 compared to those of the nonadsorbed compounds at equal concentration. For TLC this SERS effect is accomplished by spraying chromatograms with colloidal silver solution or silver coating in a vacuum chamber (post-chromatographic SERS activation in TLC). By using SERS microprobe techniques (laser spots down to $1 \mu\text{m}$ in size) and high performance thinlayer chromatography (HPTLC) plates it is possible to achieve low picogram detection limits for HPTLC spots.

Fourier Transform Infrared Spectroscopy (FTIR)

Sample Transfer TLC-FTIR

The classic approach and most frequently used method for recording infrared spectra of substances separated by TLC or HPTLC involves removal of the sample zone from the plate, usually followed by extracting the analytes via a solvent to an IR-transparent pellet or powder. This technique makes it possible to measure full IR spectra at a reasonable sensitivity using conventional FTIR transmission or DRIFT detection. Commercial accessories are available for a simple and convenient procedure for the transfer of the analyte spots to cups containing IR-transparent substrates. The use of this method has been illustrated by the analysis of dyes, quinones, coal extracts and biochemical substances. Reasonable IR spectra with full spectral features can be obtained from 1 to $0.01 \mu\text{g}$ of sample per spot. The main reason for using transfer in TLC-FTIR is to avoid the strong absorption bands in the mid-IR (400 – 4000 cm^{-1}) from the TLC stationary phase. Over the years, numerous other transfer methods for the combination of TLC or HPTLC and FTIR detection have been described in the literature. The normal method involves removal of zones (scraping off), elution of the spot analyte, deposition on the material transparent to IR and the measurement by FTIR. However, the removal of zones from the plate increases the risk of contamination and can result in further reactions. The "wick-stick" technique consists of pressing KBr micro pyramids onto the TLC plate at locations corresponding to the analyte spot. With a development perpendicular to the first development, the analytes are eluted into the pyramids, which are then dried and pressed into pellets. The Eulochrom system involves the elution of analyte zones from silica-gel TLC plates by means of small amounts of methanol, then solvent evaporation and pellet preparation. A simple and convenient procedure in conjunction with TLC sheets with a liquid-permeable support such as the Empore TLC sheet is the transfer of separated spots to a powder layer of potassium bromide. After ordinary TLC development, the sheet is put in a sheet holder chamber and a thin layer of KBr powder is applied on the upper side of the Empore TLC sheet. After this KBr coating, zones are eluted from the sheet by means of a wetted fritted glass unit and thus moved into the powder layer.

Thermal desorption FTIR analysis can be used to avoid the interference from TLC stationary phases with analyte because strong interaction between the analyte and the stationary phase causes significant

band shift. Therefore, vapour-phase spectrum libraries can be used directly for sample identification. This method can be applied to thermally stable substances which can be desorbed from thermally stable TLC stationary phases. The separated TLC spot is scraped off and loaded onto the sample pan of a thermogravimetric analyser (TGA/FTIR). Spectra are easily identified for samples present at a level of 10 µg per TLC zone. A detection limit of 0.8 µg is found for analysis of methyl benzoate.

Over the years, research and practical applications have shown that sample transfer TLC-FTIR technique (offline coupling for TLC and FTIR) can be effective and useful as a reliable TLC spot identification method.

***In situ* TLC-FTIR**

IR spectral identification of a TLC spot by means of sample transfer TLC-FTIR methods is usually time consuming and problematic. Alternatively, IR spectroscopic information about TLC-separated materials can be obtained *in situ* by means of a variety of FTIR techniques. Monitoring the TLC zones by direct DRIFT measurements, transmission spectroscopy, infrared microspectroscopic detection and photoacoustic FTIR (PA-FTIR) enables both qualitative and quantitative characterization of separated spots. To acquire useful IR spectra the *in situ* TLC spot method requires the background measurement of the adsorbent free of any sample. The final IR spectrum is obtained by either ratioing sample and background measurements or subtracting the background spectrum from the sample spectrum. This part of the *in situ* TLC-FTIR detection method is very important for the quality of the resulting analyte IR spectrum. Depending on the nature of the isolated TLC spots and the goal of the analysis, the choice of IR measurement can be either DRIFT or transmission.

Today online coupling of TLC(HPTLC) and DRIFT spectroscopy can be carried out using commercially available equipment. By combination a computer-controlled x-y stage with a specially constructed DRIFT unit and an FTIR spectrometer it is possible to obtain direct IR chromatograms of TLC spots. The chromatograms can be generated both frequency-dependent as spectral windows of a certain range and frequency-independent as a Gram-Schmidt trace. Depending on the infrared absorptivity of the TLC analyte and the distance run in the chromatogram, the limits of identification, the validated detection limits, and the limits of quantification lie between 10 ng and 2.5 µg.

In general, use of automated multiple development (AMD) for TLC separation can improve the online

DRIFT identification limit by one-third compared to conventional TLC separation techniques.

The *in situ* FTIR detection of spots on a plate by means of IR transmission measurements requires an IR transparent support, e.g. silica gel coated on AgCl plates. A thin adsorbent coating and IR transparency of the silver chloride support permits enough energy throughput to acquire analyte species at 0.1–10 µg of material. The detection limit of this technique in conjunction with programmed multiple development and special postcoatings can be improved to the nanogram level. This technique is limited to noncommercially available AgCl speciality plates.

The development of microchannel TLC spot identification with diffuse reflectance infrared microspectroscopic detection is also a method for specific practical applications. In this case a zirconia stationary phase is used instead of silica or alumina. Zirconia shows significantly higher reflectivity than silica or alumina resulting in only moderate background interferences. The detection limit for this specially prepared plate is about 1–10 ng.

Photoacoustic FTIR has been suggested as the technique of choice over DRIFT analysis of high IR-absorbing sample matrices. Photoacoustic spectrometry (PAS) is based on the phenomenon that light impinging on the solid TLC plate, can produce an acoustic signal. PAS involves therefore the measurement of oscillating pressure variations of a confined inert gas situated above the TLC plate. In combination with a PAS cell an FTIR spectrometer can yield photoacoustic IR spectra, which can be applied for TLC zone identification purposes. PA-FTIR does not require sample preparation and avoids the effects of light scattering and reflection.

TLC-NIR

Both mid-infrared (mid-IR) and NIR spectroscopy are important techniques for TLC or HPTLC spot analysis because of their sensitivity and versatility. The main difference between mid-IR and NIR is that bands in the mid-IR are primarily due to molecular fundamental vibrations, and absorption in the NIR region, 800–2500 nm, is primarily due to overtone and combination bands of, O-H, N-H, S-H and C-H functionalities. In the NIR region absorption is rather weak and TLC adsorbents such as silica gel have no strong absorption bands in these NIR regions, so background interferences are very small. Also, nearly all analytes of interest absorb in the NIR region.

Direct, *in situ* diffuse transmission FT-NIR microspectroscopic detection of separated HPTLC spots of different kinds of phospholipids give typical results

from which the usefulness of the TLC-NIR method can be evaluated. The limit of detection with a narrow NIR beam of light (0.4 mm^2) is under $1 \mu\text{g}$, and the correlation coefficient of the calibration curve is about 0.98 for phospholipid amounts from 1.25 to $10 \mu\text{g}$. Detection limits of less than $1 \mu\text{g}$ of selected sugar samples on developed TLC plates have been demonstrated with the use of NIR detection with a diffuse-transmittance geometry.

Raman Spectroscopy

TLC/Normal RS

In contrast to FTIR spectroscopy, where we have been concerned with the absorption of infrared light, RS depends on the frequency of the laser light scattered by molecules as they undergo rotation and vibration and in this respect it is similar to infrared spectroscopy. Since the selection rules are different, the information obtained from the laser Raman spectrum often complements that obtained from FTIR studies and provides valuable structural information. The intensity of Raman scattering is directly proportional to the laser excitation intensity and to the concentration of the TLC sample. This is important in quantitative studies. Therefore, laser RS can be considered as a tool for *in situ* analysis of TLC or HPTLC spots, since materials such as silica gel matrices give weak Raman spectra and minimal interference with the spectra of the adsorbed species on the TLC plate.

Using an argon-ion laser for visible excitation (488 or 514 nm) and dispersive Raman units, detection limits for different separated nonresonant substances are in the μg region. In the past *in situ* Raman microspectroscopic investigations on different TLC plates have shown that the detection limit by means of this Raman method could be improved up to the ng region. As an example, nonresonant Raman spectroscopy of representative explosive samples separated on silica gel plates have shown that visible conventional macro-sampling RS can be used nondestructively to detect and identify this substance class down to a few micrograms. The same investigations by means of visible Raman microprobe spectroscopy (scanning laser diameter of $8 \mu\text{m}$) gave improved detection of these explosive substances (the detection limit of TNT is $0.5 \mu\text{g}$).

TLC/Resonance RS

As the laser exciting frequency in the Raman experiment approaches an allowed electronic transition in the molecule being investigated, those normal modes that are vibronically active in the electronic transition

exhibit a pronounced enhancement in their Raman intensities. Most examples of resonance-enhanced RS involve the enhancement of totally symmetric modes. The resonant Raman effect can enhance Raman intensities by factors of the order of 10^5 . This means that corresponding lower concentrations of scattering molecules on the TLC spot can be used, therefore improving the detection limit. An example of the enhanced intensity from the resonance Raman effect is the investigation of silica gel TLC zones of metalloporphyrins. Using 514.5 nm excitation and an optical multichannel analyser, nanogram levels of the strong absorbing analytes (Ni-uroporphyrin, Ni-protoporphyrin) in the visible spectral range have been obtained.

TLC/FT Raman

The past few years have seen pronounced growth in the use of dispersive and interferometric RS in the field of TLC spot identification, largely attributable to increased awareness of the technique's potential as well as the new methodology and hardware. These developments include, in particular, near infrared Fourier transform Raman spectroscopy (NIR FT-Raman). Since the development of NIR lasers, both fluorescence and photodecomposition problems have been reduced or avoided in most cases. In particular, the Nd:YAG lasers emitting at 1064 nm have proven advantageous due to their long wavelength λ , high power, and stable intensity. Absorption of the TLC plates from the silica coating and the glass substrate are avoided and the full Raman spectral range may be collected without interference. Commercially available X-Y-Z stages for TLC plates can be placed directly in FT-Raman instruments and the measurement of the TLC spot taken *in situ*. One further advantage arises from the use of newly developed HPTLC plates for Raman spectroscopy (Merck, HPTLC aluminium sheet Si 60 F254s Raman). The potential and benefit of this *in situ* hyphenation of HPTLC and Raman spectroscopy in its broad spectral range, no interference by the silica matrix, identical spectra with standard Raman spectra, high sensitivity of detection and about 10-fold intensity of signal/noise compared to conventional HPTLC plates.

The feasibility of measuring the Raman spectra of chlorinated hydrocarbon pesticides on TLC adsorbents was initially studied using high concentrations (about $100 \mu\text{g cm}^{-2}$) of separated pesticides on normal silica gel TLC plates. In the case of N-heterocyclic pesticides the detection limit on normal HPTLC plates could be reduced to low $\mu\text{-gram}$ region. As an example, **Figure 1** shows the FT-Raman investigations of the MPP(1-methy-4-phenylpyridi-

Figure 1 FT-Raman spectra of the pesticide 1-methy-4-phenylpyridiniumiodine (MPP). (A) 500 ng of MPP spotted on a HPTLC silica gel 60 plate and (B) as the pure crystalline powder. Bruker: NIR FT-Raman spectrometer RFS 100; $\lambda_{\text{ex}} = 1064 \text{ nm}$, laser power 630 mW, 4 cm^{-1} resolution.

niuniodine) pesticide on a silica gel HPTLC plate and the corresponding pure material. In comparing the two spectra, no significant band shifts were observed but all bands in the spectrum of the HPTLC spot were broader than in the spectra of the polycrystalline pure substance.

In some basic experiments, the feasibility was demonstrated of obtaining artifact- and fluorescence-free spectra by *in situ* FT-Raman spectroscopy of paracetamol, fluorene and rhodamine B on silica gel TLC plates. For the strong Raman scatterer fluorene, the detection limit was found to be 500 ng for a 3 mm diameter TLC spot.

Several pharmaceutical test compounds have also been investigated and together with the use of FT-Raman spectral libraries for identification of TLC spectra and different search algorithms have been compared.

At present further work is in progress to investigate factors which could improve the *in situ* spot analysis of TLC, HPTLC and Raman-HPTLC plates by means of FT-Raman spectroscopy.

SERS Spectroscopy

The discovery that Raman vibrational signals from molecules adsorbed on nanometer scale metal particle structures are enhanced by 10^6 to 10^9 has caused extraordinary interest and excitement. This Raman technique, known as SERS offers new possibilities as a spectroscopic probe in the field of TLC separation science. It was shown that excellent Raman spectra could be obtained for low nanogram to picogram amounts of nonresonant and fluorescent substances on filter paper, paper chromatographic supports, and TLC or HPTLC plates using SERS spectroscopy.

The Raman scattering cross-section of an adsorbed molecule on nanometal structures can be further increased by utilizing a laser excitation frequency which is in resonance with an electronic transition in that molecule. This molecular resonance Raman scattering and the SERS effect can combine to give surface-enhanced resonance Raman scattering (SERRS) so that the limit of detection is further increased. Therefore, by detecting resonant molecules on TLC (HPTLC) plates in conjunction with the SERRS effect, very low concentrations have been achieved in many fields of research. Another striking feature of SERRS spectroscopy is that the fluorescence of the analyte on TLC plates can be completely quenched by the presence of a nanometal surface. Therefore, the SERRS quenching effect generates a high-quality surface Raman spectrum.

For TLC (HPTLC) this SERS or SERRS effect is accomplished by spraying chromatograms with colloidal silver solutions (reduction of AgNO_3 with NaBH_4 or citrate). In order to further improve the sensitivity of the TLC-SERS method experiments have been carried out in the field of well-defined vacuum-deposited silver films onto the separated and developed TLC plates. The TLC plates were mounted on a holder inside a vacuum chamber where silver is thermally evaporated onto the plate. The evaporation rate and the silver thickness are controlled in order to find out the most intense SERS signals. Such SERS-activated TLC plates are stable for many weeks and can therefore be considered as an 'analytical diskette' for Raman spectroscopy. In addition to these post-activation methods, two other possibilities for SERS activation can be identified: (1) the simultaneous activation of the plate with spotting of the sample, e.g. by dissolving the sample in Ag colloidal solution, (2) pre-activation of TLC plates via *in situ* decomposition of silver carboxylates.

In order to reveal the optimal conditions in TLC-SERS spectroscopy, atomic force microscopy (AFM) was applied to investigate the surface morphology of the Ag labelled TLC substance spots (colloid

Figure 2 (See Colour Plate 120) AFM photograph of a silver-coated HPTLC silica gel KG60 plate (post-overlayer SERS activation). NanoScope III; tapping mode.

TLC-SERS and overlayer TLC-SERS). **Figure 2** shows an example of the AFM picture of a post-activated silver-coated HPTLC silica gel plate in the μm scale (post-overlayer SERS activation).

TLC/VIS-SERS

The first report on the combination of planar chromatography and SERS with colourless (non-resonance Raman scatterer) analyte spots was the direct analysis of HPTLC spots of nucleic purine derivatives in 1987. After separation and drying, HPTLC plates were sprayed to wetness with colloidal silver solution by a spray atomizer. The chromatogram zones were analysed at room temperature by a computer-controlled double beam monochromator and the excitation wavelength was the 514.5 nm line of an argon ion laser. Limits of detection were estimated to be less than 5 ng/spot. Comparison of these HPTLC/VIS-SERS spectra with normal Raman spectra of molecules in aqueous solution reveals significant differences: (1) the relative band intensities are changed due to vibration-dependent surface-enhanced scattering mechanism, (2) band shifts can occur (e.g. shift of ring breathing mode of adenine from 724 to 736 cm^{-1}), (3) band broadenings were observed in the HPTLC/VIS-SERS spectra.

In clinical chemistry, immunoassay methods in conjunction with TLC play an important role in the routine determination of active substances in body fluids. For instance it is possible to separate theophylline without difficulty from its positional isomers

and from other xanthine derivatives. *In situ* identification of these compounds using online HPTLC/VIS-SERS can be performed in the ng region.

Examples of TLC/VIS-SERS measurements from many research groups have been selected to illustrate the high sensitivity, molecular specificity, accuracy, easy SERS sample preparation, and the significant manifold application.

The result of all these investigations is that the TLC/VIS-SERS detection appears to depend on different factors which must be considered before any normal application. Close approach to, or direct contact with, silver colloids of investigated analytes are a prerequisite of Raman scattering enhancement. Furthermore the size, shape, dimension and electrical charge density of the silver colloids are very important. Control and optimization of all these parameters would increase the feasibility of TLC/VIS-SERS *in situ* detection to a maximum number of chemical compounds separated on TLC(HPTLC) plates.

TLC/SERRS

The surface-enhanced resonance Raman effect in the field of chromatogram spot identification, first reported in 1984 by Tran (see Further Reading), has led to the study of a variety of separated dye molecules with different chromatographic techniques. Three structurally similar dyes, crystal violet, malachite green and basic fuchsin were chosen in order to show the potential of SERRS for the direct identifica-

tion of chromatogram spots separated by means of paper chromatography. The detailed vibration spectra allowed identification and the limit of detection was 2 ng cm^{-2} .

After this work, different types of dyes, TLC (HPTLC) plates, the role of the supporting matrix and sol preparation protocols were investigated and examined for their influence on the SERRS signal. The investigations of all these effects and the construction of a remote sensing Raman spectrometer to investigate the model compound pararosaniline resulted in the maximum SERRS intensity yielding a detection limit of about 108 femtomol (33 pg) of this pararosaniline dye.

Another very interesting application is the incorporation of SERRS as a detector for a liquid chromatography (LC)-coupled TLC system. In this SERRS/LC/TLC system, effluent from the LC system was deposited onto the TLC plate and an activated Ag sol was added to the plate. Optical fibres carried the 514.5 laser light to the TLC plate and the scattering radiation to the Raman spectrometer. The dye molecule, pararosaniline acetate, was found to give a linear SERRS signal over the concentration of 1×10^{-5} to $1 \times 10^{-7} \text{ M}$ range and the limit of detection was 750 fmol.

The measurements of other highly fluorescent molecules such as acridine orange, rhodamine, Glu-P2 as well as N-containing PAHs separated on HPTLC plates have shown that the sensitivity is so high that *in situ* vibrational investigations are possible with low picogram amounts of material.

Today, it is clear that TLC/SERRS spectroscopy can be widely applied to obtaining structural information about very small amounts of coloured substances (dyes, pigments) separated by TLC or HPTLC.

TLC/Micro-SERS

Following the rule that 'an optimized Raman scattering sample is a micro sample' Raman microspectrometers have been designed for investigation of small particles in the μm range. Although there is earlier work in the coupling of a microscope and a Raman spectrometer, by far the largest amount of work has been carried out in the past 10 years. The new generation of Raman microprobe spectrometers comprise modern monochromators with notch filter systems, charged coupled device (CCD) detectors and confocal optics. This type of laser confocal Raman microspectrometer permits the acquisition of Raman spectra from TLC(HPTLC) spots down to $1 \mu\text{m}$ in size and allows the unambiguous placement of the laser focus at the chromatogram with a spatial resolution of $1 \mu\text{m}$.

In the first study on HPTLC/Micro-SERS, a Raman microspectrometer consisting of an argon ion laser, a microscope, a triple monochromator and a multi-channel detector was used. With this system it was possible to acquire VIS-SERS spectra of silica gel HPTLC spots of DNA bases and dibenzofuran at the low picogram level. Considering the fact that the laser focus is about $1 \mu\text{m}$, the irradiated spot mass is only a few femtograms. Combining this microsurface-enhanced Raman scattering and HPTLC has also enabled *in situ* analysis of chromatogram spots of cationic surfactants in amounts down to subnanogram levels.

Micro-Raman equipment and the SERRS effect have been used for selective detection of structurally similar aminotriphenylmethane dyes separated by HPTLC. *In situ* SERRS spectra were recorded after the application of aqueous Lee-Meisel hydrosol solution (reduction of silver nitrate with sodium citrate) to the analyte spot. The limits of identification of the dyes are of the order of 5 ng (applied amount).

Recently the optical detection and spectroscopy of single molecules and single nanoparticles was achieved with the use of SERRS spectroscopy for rhodamine 6G adsorbed on selected silver nanoparticles. This was the first application of Raman spectroscopy in the field of 'probing single molecules by means of Raman vibration spectroscopy'.

As a result of the dramatic improvement of the sensitivity in the coupling of TLC and SERRS microspectroscopy, it is possible to probe low numbers of molecules on TLC plates. Figure 3 shows the high sensitivity of TLC/Micro-SERRS spectroscopy by demonstrating the identification of rhodamine 6G on a HPTLC plate at a concentration as low as $1 \mu\text{L}$ of 10^{-10} M solution applied on the plate. Considering the fact that the 488 nm laser spot is only $1 \mu\text{m}$ in diameter, the number of R6G molecules in the analysed area are substantial between 400 and 600.

Figure 4 shows the topography of a selected area from the silver colloidal SERS activated silica gel (KG60) HPTLC spot of R6G. This AFM picture clearly shows the Ag nanoparticle adsorbed on the silica gel particles of the HPTLC plate. Depending on the colloid aggregation on the substance/silica zone, the diameter of the Ag particles is in the region between 10 and 60 nm.

According to the short range sensitivity of SERRS (about 1 nm from the surface) the spectra obtained from the HPTLC spot are attributed to molecules which have a direct contact to the surface of the colloids.

Figure 3 HPTLC/SERRS microprobe analysis of rhodamine 6G. 1 μL of 10^{-10} M R6G applied on the silica gel (KG60) HPTLC plate. 1 μm selected with the focused laser beam. Laser excitation line, 488 nm; laser power at the spot, 8 mW; integration time, 3 s; number of reads, 80. Number of molecules in the scattering volume 400–600 R6G molecules.

TLC/FT-SERS

Some years ago, NIR FT-SERS spectroscopy was suggested as an alternative experimental method to conventional dispersive Raman spectroscopy in TLC/SERS. Because of the NIR excitation at 1064 nm and the fluorescence-quenching effect of the SERS effect, TLC plates containing indicator could be used without any problem. In the first TLC/FT-SERS experiments, good-quality FT-SERS spectra of a spot of 40 ng rhodamine B was recorded after spraying with a silver colloid solution. These preliminary results have shown that the SERS effect also works on TLC plate spots in the NIR spectral range. In general, it was also found that the enhancement factor at 1064 nm excitation was increased by one or two orders of magnitude as compared with the 514.5 laser excitation.

Direct analysis of sub-femtogram quantities of carotenoids on different types of TLC plates has been made possible by associating FT-Raman micro spectroscopy with the SERS effect. In this HPTLC/micro-FT-SERS experiment, detection of 10^{-5} M crocetin corresponded to a deposited mass of 1.65×10^{-8} g, thus in the 8 μm laser spot an analysed mass of 0.02 fg. These postactivation SERS investigations have also shown that SERS intensity is not dramatically influenced from the TLC layer thickness, particle size distribution, mean particle size and presence or absence of a fluorescence indicator.

Figure 4 (See Colour Plate 121) AFM (tapping mode) surface plot of a silver colloidal SERRS activated silica gel plate (KG60, Merck). A selected $X = Y = 500$ nm spot area of a 1 μL of 10^{-10} M rhodamine 6G spotted on the plate. The silver hydrosol marker has a diameter of between 10 and 60 nm.

Figure 5 HPTLC/FT-SERS analysis of metamitron on a KG60 plate with a silver-coated layer of 20 nm thickness. 1 μ L of 10^{-5} M metamitron spotted on the KG60 plate. Bruker: NIR FT-Raman spectrometer RFS 100 S; $\lambda_{\text{ex}} = 1064$ nm, laser power 400 mW, 4 cm^{-1} resolution.

The possibility of TLC/FT-SERS pre-activation of TLC plates has been demonstrated for heterocyclic and aromatic species (pyrene, anthracene fluoranthene, biphenyle and benzoquinoline). The pyrolysis of pre-deposited silver oxalate forms FT-SERS system based on TLC plate. This thermal decomposition of silver oxalate represents a new, simple method of pre-activation in TLC/FT-SERS spectroscopy. The disadvantage is that R_F values on these pre-activated TLC plates are strongly influenced by the Ag clusters on the plate. Therefore, in this case one has new separation conditions on the TLC plate.

The most useful and effective method for TLC/FT-SERS spectroscopy is the postchromatographic silver coating of the TLC plate inside a vacuum evaporator (overlay TLC/FT-SERS). As an example to demonstrate this new technique, a HPTLC/FT-SERS spectrum of metamitron (1 μ L of 10^{-5} M metamitron spotted on HPTLC-KG60 plate) which was coated with a 20 nm thick layer of silver, is shown in **Figure 5**. Therefore this overlay TLC/FT-SERS spectroscopy is very suitable for the investigation of separated pesticide spots on TLC plates.

As a consequence of their advantages the combination of TLC/FT-SERS techniques with silver coating of the TLC plate inside a vacuum evaporator will extend the use of surface-enhanced Raman spectroscopy to a much greater range of samples than examined so far.

Conclusion

The examples of the coupling of TLC and vibration spectroscopy in the separation technique reviewed in this article have been selected to illustrate the sensitivity, molecular specificity of separated substance zones, accuracy, ease of sample preparation, and the many significant applications of FT-IR, Raman analysis and SERS spectroscopy for substances in the adsorbed state on TLC (HPTLC) plates. The sensitivity and rich spectral information that FT-IR, Raman and SERS provide have spurred the rapid development of technology for using vibration spectroscopy as an analytical detection method of separated TLC spots. With the extremely high enhancement of the Raman scattering signals on SERS-activated TLC plates it is possible to identify *in situ* separated TLC spots at the pico- and femtogram level. Further work is in progress to investigate factors which could improve the utility of vibrational spectroscopy in chemical structure elucidation of separated TLC zones.

TOBACCO VOLATILES: GAS CHROMATOGRAPHY

W. M. Coleman, R. J. Reynolds Tobacco Company,
Winston-Salem, NC, USA

Copyright © 2000 Academic Press

Introduction

The leaves of tobacco plants, *Nicotiana tabacum*, have been shown by Tso and Stedman to consist of a wide array of organic and inorganic compounds. For general classification, the components of the leaf can be described as volatile, semivolatile and non-volatile. The nature of the compounds making up the components of the leaf range from nonpolar constituents such as hydrocarbons to very polar compounds such as carboxylic acids and amines. The structural identity of these components has been determined in many laboratories, including those of DeMole and Lloyd, through the use of classical wet chemical separation techniques coupled with end determinations involving, in some cases, further separations by gas chromatography (GC). In some cases, headspace volatiles have been trapped on Tenax or charcoal then either thermally or solvent desorbed. Supercritical carbon dioxide has also been used for extraction. In some of the earlier work, the separations were performed on packed glass GC columns and somewhat later on coated glass columns.

With the advent of multidimensional GC (MDGC), the labour-intensive sample preparation techniques associated with wet chemical separations of selected fractions were for the most part eliminated. With the MDGC approach, a concentrated solution of a tobacco essential oil in a volatile organic solvent can be directly injected on to a fused silica capillary pre-column, followed by heart-cutting on to another column. The phase of the pre-column of the MDGC system essentially serves as a replacement for the wet chemical separation approach. In this way, as many

as 80 new compounds were tentatively identified in a flue-cured tobacco essential oil. Detection and identification of the volatile components of the essential oils were possible through the use of mass selective detectors and matrix isolation Fourier transform infrared spectroscopy.

Another approach for the lower molecular weight volatiles employed automated purge-and-trap (P & T)-GC with flame ionization (FID) and mass selective detection (MSD). A relatively nonpolar DB-5 ((5% phenyl)methylpolysiloxane) column was employed for the separation of the volatiles. In further advances on the P & T method, the influences of ionic strength and pH on the yield of volatile materials have been reported. By employing a cryofocusing approach coupled with a DB-1701 ((14% cyanopropyl-phenyl)methylpolysiloxane) fused silica column of intermediate polarity, and an internal standard, semiquantitative analytical data were provided on the volatiles from a variety of natural products.

Through the use of multiple fused silica GC columns of different bonded phases, a universal commonality describing the nature of the volatile materials from a wide range of natural products has been developed. The types and profiles of volatile low molecular weight compounds found in the headspace above tobacco leaves has been shown to bear remarkable similarities to the profiles from a diverse array of heat-treated natural products such as coffee, peanuts and soybeans. The common thread linking all of the products has been ascribed to the presence of specific reactions between amino acids and other nitrogen sources with sugar molecules to yield volatile components such as pyrazines and aldehydes. For details of the work outlined in this section, see the papers by Coleman *et al.* in the Further Reading section.

This article describes the current GC approaches to the analysis of volatiles from tobacco. Results are described on approaches involving dynamic headspace-GC-MSD, as well as automated solid-phase microextraction (SPME)-GC-MSD.

Experimental

Dynamic Headspace P & T-GC-FID-MSD

Solid samples Representative samples of dry cured tobacco leaves were finely ground in a coffee grinder prior to analysis. After grinding, the moisture content of the tobacco leaves was adjusted to 20% by weight and the samples were allowed to age overnight at room temperature ($\sim 23^{\circ}\text{C}$). Finely ground moisture-adjusted tobacco leaves (3–5 g) were placed in a 25 mL sampling tube and affixed to the sampling port of a Tekmar LSC 2016/LSC 2000 P & T unit. Six replicates were run to obtain adequate statistical analyses. Average % relative standard deviation values for the total FID area counts for the solid samples were approximately $\pm 10\%$. After reaching the desired temperature, the contents of the 25 mL sampling tube were swept with helium, at a known flow rate for a specified length of time. The volatiles in the gas stream were efficiently trapped on a Tenax column (12 in \times 1/8 in i.d. SS tube) held within the Tekmar LSC 2000 unit. After sweeping the sample, the contents of the Tenax trap were thermally desorbed and transferred via a heated, aluminium-clad, deactivated, 0.53 mm i.d. fused silica transfer line to the injection port of a Hewlett Packard (HP) 5880 GC set at 250°C . Liquid nitrogen was employed to cool the GC oven to 0°C during the transfer of the volatiles. Upon completion of the transfer, the GC oven was temperature-programmed up to 250°C . The effluent from the DB-1701 column was split via an SGE low dead-volume splitter to the FID and MSD detectors at a ratio of 20 : 80. An HP 5970 Mass Selective Detector operation at 70 eV in the electron impact mode served as the MSD. The analyses were automated by means of basic programming of the HP 5880 GC terminal. The parameters employed in the analysis of the volatiles from solid tobacco leaves are listed in Table 1.

The volatile constituents were identified with the aid of GC retention indices as well as results of library mass spectral searches of Wiley, NBS and internal mass spectral databases.

Aqueous liquids and suspensions To a 5 mL sparge tube was added 1 mL of the tobacco liquid extract or suspension. The sparge tube was affixed to the Tekmar LSC 2016. Analysis then proceeded as described in the preceding section.

Table 1 Instrumental parameters for P & T-GC-MSD-FID analyses

Sample volatilization temperature	70°C
Sample volatilization time	20 min
Trapping material	Tenax
Trap desorption temperature	175°C
Trap desorption time	10 min
GC oven initial temperature	0°C
GC oven first programme rate	$2^{\circ}\text{C min}^{-1}$
GC oven final value	47°C
GC oven second programme rate	$10^{\circ}\text{C min}^{-1}$
GC oven final value	250°C
GC oven final time	10 min
GC column	DB-1701
GC column length	30 m
GC column i.d.	0.32 mm
GC column film thickness	1 μm

Automated SPME-GC-MSD

Aqueous liquids and suspensions A Varian 8200 CX AutoSampler with SPME II Sample Agitation was mounted on top of an HP 5890 Series II Plus GC equipped with a HP 5972 MSD operating either in the electron impact mode at 70 eV or in the selected ion monitoring (SIM) mode. This GC was fitted with a relatively polar DB-Wax (polyethylene glycol (PEG)) fused silica column (30 m \times 0.25 mm i.d., 0.5 μm film thickness, J & W Scientific). The MSD interface and GC injection port temperatures were 250°C . The GC oven was temperature-programmed from 40 to 140°C at $5^{\circ}\text{C min}^{-1}$, then to 220°C at $10^{\circ}\text{C min}^{-1}$ and held there for 4 min. Splitless injections were made and the split was opened after 1 min. The fibre was automatically submerged in the solution, vibrated for 0.75 min, removed, injected, and held in the injection port for 30 min, employing parameters set via operating software.

SPME fibres for automated injections were obtained from Supelco and employed strictly following the manufacturer's instructions for use and activation.

Prior to analysis by automated SPME, the aqueous heat-treated tobacco suspensions were manually filtered through a Whatman Autovial equipped with a 0.45 μm polyvinylidene fluoride filter and designed for use with aqueous solutions. Then, to a 1.8 mL vial equipped with Teflon-lined septum, was added, via a Rainin EDP Plus Motorized Microliter Pipet, 1.7 mL of the filtered solution. Strict attention to consistency in the addition of 1.7 mL was necessary to obtain reproducible results. The charged vials were loaded on the sample carousel and automatically sampled employing the instrumentation software provided by Varian and HP. In some cases it was necessary to dilute the heat-treated suspensions to obtain reproducible

fibre performance. Fresh samples were used for every injection.

SIM was used for the quantitative determination of selected pyrazines in the heat-treated suspensions. The selected compounds and accompanying selected ions (m/z) are listed as follows: methylpyrazine, 94, 95, 96; C2 pyrazines, 107, 108, 109, 110; C3 pyrazine, 121, 122, 123, 124 and C4 pyrazines, 135, 136, 137 and 150. The C2, C3 and C4 notations are used to denote a class of pyrazines. For example, C2 pyrazines would include all of the dimethylpyrazines as well as ethylpyrazine. Identical arguments are used for the C3 and C4 terms.

Discussion of Results

The distinct aromas associated with such materials as cured tobacco, roasted peanuts, roasted coffee and baked bread are familiar to most people. The identity of a large majority of these volatile aromatic components has been published recently. Within the tobacco industry, skilled individuals can easily distinguish between the types of tobacco employed in American blended cigarettes. This is not surprising in light of the unique patterns of the headspace volatiles found for these tobaccos (**Figure 1**). In a number of cases, some of the volatiles found in the headspace above the tobaccos are common to all of them and the main difference lies in the relative amounts of these common volatiles. For example, 2-butanone was common to three tobacco samples; however, the relative amounts were significantly different. In 1996 Coleman *et al.* demonstrated that this quantitative difference in the amount of specific headspace volatiles is common to a diverse array of natural products.

Use of the DB-1701 column with intermediate polarity served very well in providing sufficient resolution to assist in identifying the vast majority of compounds. Some of these compounds are listed in **Table 2** with numbers which correspond to peak identities throughout the entire manuscript. Each of the components listed in **Table 2** has been previously identified by Tso and Stedman in tobaccos. Thus, P & T-GC-MSD is a viable approach for the identification and segregation of tobacco types.

Roasting of natural products has often been associated with the production of pleasant aromas and tastes. In some cases these pleasant sensory responses have been attributed to the presence of low concentrations of volatile pyrazines and aldehydes. The presence of these compounds has been linked to the reaction of nitrogen sources such as amino acids with carbon sources such as sugars. Toasting of burley

tobacco leaves at approximately 150°C for 5 min produces an aroma associated with toasted natural products. Analysis of the headspace above the toasted burley tobacco reveals the presence of low molecular weight compounds also found in other heated natural products (**Figure 2**).

Increased levels of the Strecker aldehydes, 2-methylpropanal, 3-methylbutanal and 2-methylbutanal, relative to the starting tobacco are leading indicators of the sugar–nitrogen reactions. The reaction to form Strecker aldehydes is one of a series of complex reactions, collectively referred to as the Maillard reaction, occurring simultaneously between nitrogen sources such as amino acids and sugars during the heat treatment of natural products. When valine, leucine, isoleucine, phenylglycine and phenylalanine react with, for example, fructose at elevated temperatures, the following Strecker aldehydes are produced: 2-methylpropanal; 3-methylbutanal; 2-methylbutanal; benzaldehyde; and benzeneacetaldehyde. Thus, the presence of these compounds in the headspace above heat-treated natural products serves as an excellent indicator of amino acid–sugar reactions. In addition, an increased amount of volatile pyrazines in the headspace above heated natural products serves as a witness to the reaction between nitrogen sources and sugars. Further changes can be noted in the profile of the toasted burley relative to the starting material. Substantial increases in the relative amounts of solanone, neophytadiene and damascenone, all known burley constituents, can be found in the toasted material (**Figure 3**).

As before, the intermediate polarity of the DB-1701 column served well in providing sufficient chromatographic resolution of the volatile components.

Cooking natural products to produce edible materials with positive sensory attributes in some instances occurs in what can be viewed as an aqueous suspension. Boiling rice, beans or cooking a roast under pressure are simple examples. It has been shown that heat treatment of an aqueous suspension of burley tobacco, at 170°C for 30 min, produces some similar volatile materials (**Figure 4**) as are found in the headspace, for example, above a heat-treated peanut suspension. The headspace of both samples is dominated by the presence of Strecker aldehydes, sugar thermal degradation products and pyrazines. On a relative basis, the volatile materials detected in the heat-treated suspension were not detectable in the starting tobacco. The volatile components in the heat-treated aqueous burley tobacco suspension were also indicative of the sugar–nitrogen chemistries known to produce Strecker aldehydes and volatile pyrazines when heating tobacco alone.

Figure 3 Structures of some compounds present in heat-treated tobaccos.

Certain amino acids have been postulated in model systems by Waller and Feather to be directly involved in the production of pyrazines and selected aldehydes by means of the Strecker degradation mechanism. That is, upon reaction with selected sugars, certain

Table 2 Compounds identified and numbered in selected figures

^aPyrazines such as dimethylpyrazine and ethylpyrazine.

^bPyrazines such as methylethyl pyrazines.

Figure 4 Headspace volatiles from dynamic headspace analysis of (A) burley tobacco and (B) a heat-treated burley tobacco suspension.

amino acids will yield volatile aldehydes corresponding in large part to the structure of the parent amino acid backbone. Specifically, for example, phenylalanine upon reaction with sugars yields as a volatile aldehyde benzaldehyde, while valine will yield 2-methylpropanal. Dynamic headspace analysis of aqueous suspensions of burley tobacco with mmole quantities of added phenylalanine and valine show elevated levels of benzaldehyde and 2-methylpropanal (Figures 5 and 6) respectively. These results provide the first evidence implicating the Maillard and Strecker reactions within a tobacco matrix. Again, the DB-1701 GC column provides the necessary resolution.

Recently, manual SPME-GC-MSD has been shown to be an excellent analytical approach for the quantitative determination of volatile components associated with heat-treated natural products. Specifically, the quantitative analysis of pyrazines, furfurals, thiazoles and pyridines has been demonstrated in aqueous media. With the introduction of an automated injection system analytical precision has improved. Application of automated SPME (AutoSPME)-GC-MSD to the analysis of a heat-treated tobacco suspension revealed some of the first insights

into a variety of reaction mechanisms occurring during the heating process (Figure 7). The origin of pyridine, myosmine, β -nicotyrine and pyrrole-2-carboxaldehyde can probably be directly linked to the decomposition of the alkaloid, nicotine. The origin of the pyrazines is no doubt related to sugar-nitrogen reactions (see above), and the furans can be attributed to the thermal decomposition of sugars. Searches for the appropriate SPME fibre resulted in the selection of a carboxenpolydimethylsiloxane fibre. This particular fibre is suited to the analysis of relatively polar compounds in aqueous solutions. The best column for the analysis was found to be a relatively polar DB-Wax, which provided the most information concerning the reaction mechanisms.

Further application of AutoSPME-GC-MSD in the SIM mode has provided additional insights into the formation of volatile pyrazines during the heat treatment of aqueous tobacco suspensions. Model studies indicate the formation of pyrazines through the coupling of two molecules (Figure 8). Thus, should the source of the N in the two molecules be ^{15}N , then the possibility of changes in the m/z values for pyrazines could be either one or two. For example, the m/z for methylpyrazine could be changes from

Figure 5 Headspace volatiles from dynamic headspace analysis of two tobacco dusts: (A) tobacco dust plus phenylalanine; (B) tobacco dust.

Figure 6 Headspace volatiles from dynamic headspace analysis of tobacco dust suspensions. (A) Tobacco dust plus valine; (B) tobacco dust.

Figure 7 Total ion chromatogram from AutoSPME of aqueous heat-treated tobacco suspension using a carboxen polydimethylsiloxane SPME fibre.

Figure 8 Formation of methylpyrazine from two molecules.

a molecular ion of 94 to molecular ions of either 95 or 96. In other words, the distribution of the ions $m/z = 94, 95, 96$, would substantially change if ^{15}N were incorporated into the methylpyrazine molecule. Model studies have also indicated that a possible source of nitrogen for the formation of pyrazines is the ammonium ion. Labelling the ammonium ion with ^{15}N would seem to be a viable approach for determining one of the possible mechanisms associated with pyrazine formation in a heat-treated tobacco matrix.

Thus, to an aqueous tobacco dust suspension was added a mmole quantity of $^{15}\text{NH}_4\text{OAc}$. A control reaction was also performed with no additive. After heat treatment at 170°C for 30 min in a sealed reactor, AutoSPME-GC-MSD-SIM was performed on the

filtrate (Figure 9), with the focus on methylpyrazine. Alteration of the m/z pattern observed for the methylpyrazine produced in the control experiment was definitely evident. The shift in abundance toward the ions $m/z = 95$ and 96 directly implicated the inclusion of both one and two ^{15}N atoms into the methylpyrazine molecule, obviously from the added $^{15}\text{NH}_4\text{OAc}$. Thus, for the first time, by employing AutoSPME-GC-MSD-SIM, a direct link between the presence of naturally occurring reagents such as ammonium ions and the production of volatile aromatic compounds such as pyrazines has been clearly demonstrated.

Conclusion

GC in combination with such sample preparation techniques as automated dynamic headspace and SPME has been demonstrated to be an effective analytical tool for the qualitative and quantitative examination of tobacco volatiles. Through the use of an MS detector in the SIM mode, understanding has been acquired of the formation of the volatiles on a molecular basis.

TOXICOLOGICAL ANALYSIS: LIQUID CHROMATOGRAPHY

Introduction

With the introduction of high performance liquid chromatography (HPLC) coupled to detection systems providing spectral information (e.g. photodiode array detection and mass spectrometric detection, HPLC-DAD and LC-MS) the development of HPLC methods for broad-spectrum drug screening has attracted great interest in forensic laboratories. The information obtained by these methods is two-fold, i.e. retention data and spectral information, creating a powerful identification system. The growing literature describing HPLC as a broad-spectrum technique demonstrates its unique and essential position in toxicological investigations.

A number of important parameters in toxicological screening by HPLC include column packing material, column dimensions, detection, standardization and peak purity assessment. These topics will be treated while the applicability will be demonstrated by presentation of selected examples of general screening and specific detection of a limited number of compounds.

Column Packing Materials**Underivatized Silica**

Unmodified silica can retain drugs by a weak cation exchange mechanism and was used for broad-spectrum drug screening as early as 1975. The main problem, however, with the use of underivatized silica is the substantial variability of this material. Different brands of silica and even different batches

of the same brand of silica packing material often result in different retention of selected basic drugs. As a consequence, chromatographic conditions (same batch of same brand of packing, eluent composition, temperature control) need to be exactly defined and strictly followed before reproducible retention times or *retention factors* (k) can be obtained in one laboratory or in different laboratories (the latter being even more difficult). The impact of all these parameters on retention is more substantial in an adsorption system than under reversed-phase conditions. Due to these difficulties, the use of underivatized silica in the application of adsorption chromatography to systematic toxicological analysis (STA) remains rather limited.

Bonded-phase Packing Material

Bonded-phase chromatography, and more especially reversed-phase chromatography on octyl- or octadecylsilica, is by far the most popular liquid chromatographic technique used in STA. In the early 1980s valuable methods for basic drugs on modified silica began to appear. Also practical solutions to the tailing problem were established and refinements were under investigation. Free silanol functions are known to have a marked influence on retention behaviour of different drugs. These silanol effects can be reduced by changing the pH of the eluent or by addition of competing aliphatic bases (amine modifiers) as surface masking agents. Various manufacturers have launched specially prepared columns claimed to be free of silanol effects and providing more reproducible retention times. This is mainly achieved by deactivation of the free silanols by various endcapping procedures and by elimination of the trace metals from the silica support.

Alternatively, polymeric stationary phases have also been introduced. However, although the ability to run these packing materials at pH values even higher than 9 permits the analysis of basic drugs as un-ionized compounds without tailing, these polymeric phases have only a limited application in systematic toxicological analysis.

Recently, again in an effort to eliminate chromatographic problems due to residual silanol groups and to prevent the incorporation of buffer salts in the eluent, an alumina-based packing material coated with polybutadiene has also been used for broad-spectrum drug screening purposes. The inherent absence of silanol functions on this packing material simplifies the retention mechanism, eliminates the need for addition of amine modifiers and prevents irreversible adsorption of co-extracted impurities. In addition, aluminum oxide as well

as the polybutadiene coating are stable in the pH range of 2 to 12. This polybutadiene coating has hydrophobic properties comparable to reversed-phase packing materials. Consequently the same solvent mixtures can be used as in reversed-phase chromatography. By incorporation of NaOH in the eluent ($0.0125 \text{ mol L}^{-1}$), basic drugs can be chromatographed without tailing. Of course, this high pH results in poor retention of phenolic compounds (e.g. morphine) or carboxylic acids (e.g. benzoylecgonine). The latter compounds need to be chromatographed on a second and classical reversed-phase packing material. This approach of using two different and complementary packing materials is certainly not unique in systematic toxicological analysis.

Chromatographic Conditions

Due to the large differences in polarity of the compounds encountered in broad-spectrum screening and in view of simultaneous chromatography of parent drugs and metabolites in nearly all reversed-phase chromatographic systems, gradient elution is used. The few systems based on adsorption chromatography apply isocratic elution.

In LC-MS the choice of the solvent composition is limited. The use of nonvolatile mobile phase constituents (e.g. phosphate buffers) is absolutely prohibited. This limits the practical use of LC-MS by excluding techniques like ion pair and ion exchange liquid chromatography.

Offline sample preparation procedures based on liquid-liquid extraction or solid-phase extraction are not really the subject of this article. However, automation of solid-phase extraction coupled directly with injection and chromatographic analysis and on-line enrichment based on the use of two or more high pressure columns or cartridges (column switching) are already commercialized for broad-spectrum screening in toxicological analyses and therefore worthy of mention.

Detection Systems

Besides retention data, spectral information is essential for the positive identification of an unknown substance. Therefore, detection systems not providing spectral information (e.g. fixed wavelength UV detection, electrochemical detection) have found only limited application in toxicological laboratories such as for repetitive analysis of a small group of structurally similar compounds (e.g. epinephrine, norepinephrine in the case of electrochemical detection).

Photodiode Array Detection

The introduction of diode array and fast-scanning absorption detectors allowed the acquisition of UV (and visible) spectral data during the chromatographic process. This combination of the discriminatory power of the chromatographic retention parameters (which is lower for HPLC than GC) with that of the UV spectral data increased the overall reliability of an HPLC analysis in the area of toxicology. Standard reference spectra can be stored in a database tagged with parameters of retention in order to restrict the search into a window around each retention parameter.

The major problem in the identification of unknown compounds by a UV spectral match is the lack of fine structure in the UV spectrum of many compounds. The identification of metabolites is also difficult because biotransformations do not always result in a drastic change of the UV spectrum. Several studies from the area of chemometrics have provided models for UV spectral matching methods used for toxicological drug analysis. Peak maxima, calculation of differences between normalized spectra and between first-derivative spectra are thereby essential data for estimations of similarity or dissimilarity.

Ideally, each toxicological laboratory should build up its own library of UV spectra recorded under stringent chromatographic conditions. Analysis of unknown samples and recording unknown UV spectra should then be performed under exactly the same chromatographic conditions (column, eluent composition, gradient, pH, etc.) because at least the last three of these parameters can affect the observed absorbance. Another source of library variability is detector-to-detector variation. Because different photodiode array detectors use different numbers of diodes, a UV library development on one system may not be able to meet the same criteria on another instrument.

Co-elution of drugs with other drugs or with endogenous co-extracted substances remains one of the major causes of errors in HPLC analysis. Erroneous conclusions can be drawn if a co-eluting compound mimics the UV spectrum of a known compound or when the co-elution of two compounds results in a spectrum that does not match any library spectrum. Therefore, before running a library search, peak purity assessment is essential. This can be done either manually by comparison of the spectrum at different positions of the emerging peak, or alternatively some computer programs automatically indicate the peak purity under each peak in the chromatogram. The software of the more sophisticated systems even allows peak deconvolution of two co-eluting compounds, resulting in the specific UV spectrum and

quantitative contribution of each compound. Other software systems claim to be able to determine the individual drugs from a UV spectrum even if this is a result of up to six compounds eluting at the same retention time. However, it should be notified that in the latter case previous information on the probable co-eluting drugs is essential. This can be obtained from other chromatographic techniques.

Mass Spectrometric Detection

The combination of liquid chromatography and mass spectrometry (LC-MS) offers a major improvement regarding drug identification compared with the above-mentioned HPLC-DAD combination.

The improved resolution and the higher separation efficiency together with the desire to interface HPLC with mass spectrometric detection have been the major driving forces behind the development of capillary LC. Unlike GC, interfacing problems between LC and MS are still a challenge for researchers. Since the early 1970s interfaces have been constructed each applying a different technique to eliminate the chromatographic eluent, which of course cannot be introduced directly into the high vacuum region of a mass spectrometer. At least seven major interfacing techniques exist, i.e. moving belt (MB), particle beam (PB), direct liquid introduction (DLI), fast atom bombardment (FAB), thermospray (TS), electrospray (ES) and atmospheric pressure chemical ionization (APCI).

It is beyond the scope of this contribution to give an extensive overview of these different techniques. However, the respective advantages and/or disadvantages of a number of these techniques, especially in view of their application to broad-spectrum screening, will be presented. Both the DLI and the MB techniques have only historical interest and have virtually disappeared from the area of toxicological analysis. Particle beam and FAB proved to be valuable for specific applications such as the detection of steroids (PB) or the detection of compounds with high molecular mass (FAB). However, in other applications sensitivity is often a problem for these two techniques. Of primary interest for toxicological analysis are the three remaining techniques: thermospray, electrospray and atmospheric pressure chemical ionization. Because TS is able to handle flow rates of conventional HPLC systems ($1\text{--}2\text{ mL min}^{-1}$) it became the first popular HPLC-MS interface to be used in many fields with a high sensitivity. Because the ion production in this technique is dependent on the solvent composition, the application of TS with gradient elution can result in difficulties.

Electrospray operates without heat in the spray ionization step which makes this technique suitable

for thermolabile compounds, such as sulfate conjugates of drugs.

Both ES and APCI have found a wider use during the last decade with APCI having an excellent sensitivity especially for hydrophobic compounds. Electrospray has the advantage of being applicable to a wide range of analyte polarity.

Looking to the number of applications and keeping in mind that ES and APCI have not yet been exploited to their full potential, these two techniques together with TS are the most interesting techniques for toxicological analysis. The three techniques are based on a relatively soft ionization process so the mass spectra obtained sometimes lack the fragment ions necessary for confirmation of the identity of an unknown compound.

Quadrupole mass spectrometers are used most frequently because of their ruggedness, however, ion trap instruments are becoming more and more common in STA. Coupling to an ion trap spectrometer is interesting for a variety of reasons, e.g. economical aspects, sensitivity and the ability to run MS-MS experiments. Other techniques, such as collision-induced dissociation in tandem mass spectrometric configurations are also becoming available.

Reliability of Retention

As already mentioned, the efficiency of a HPLC system is considerably less than that of a capillary GC set-up so the risk of co-elution is greater. In addition, the retention behaviour of a compound (together with the spectral information, a pivotal criterion for identification of an unknown substance) is often imprecise. Batch-to-batch variation and variation of

packing materials between different manufacturers result in inconsistent retention data. In addition, coating of the active sites by irreversible adsorption and loss of the bonded-phase by ageing of the column can also contribute to changes in retention. Of course this problem can be overcome by injection of the authentic standard directly after the tentative identification of a compound. This procedure, however, is time consuming and presupposes prior identification even without a perfect match of the retention time and the availability of a pure standard. Several studies have evaluated the use of homologous hydrocarbon series, multiple drug reference standards and nitroalkanes to minimize the effect of irreproducible HPLC retention data. Although these relative retention procedures improve the reproducibility, it is difficult to obtain linear relative retention scales by using a homologous series of compounds during gradient elution, the latter being the most popular technique for liquid chromatographic toxicological screening purposes. The use of multiple drug standards instead of non-drug compounds such as nitroalkanes results in a more effective correction for retention shifts. Both principles can also be combined by calculation of retention indices of compounds from their retention times by linear interpolation between standard drugs, whose retention indices have been previously determined on a nitroalkane scale.

Applications

A number of recently developed broad-spectrum screening procedures based on HPLC-DAD are brought together in Table 1. They all use

Table 1 Operating conditions of HPLC-DAD in toxicological broad-spectrum screening

reversed-phase packings on either a silica or an alumina matrix. All except two procedures apply gradient elution and standardization of the retention is rather an exception (two procedures out of seven). The authors present lists of a large number of drugs and toxicologically relevant compounds (ranging from 130 to 600) and state that this is not a limitation but that other compounds can also be added to these lists.

It is not possible to give a similar table showing the operating conditions of LC-MS applied to broad-spectrum screening in forensic sciences. Screening the literature rapidly demonstrates that to date LC-MS has only been applied to selected compounds or groups of compounds such as steroids, thiourea pesticides, mycotoxins, tricyclic antidepressants and 10 illicit drugs (all by TS), diuretics, non-steroidal anti-inflammatory drugs, carbamate pesticides (by ES) and β -agonists, carbamate pesticides and alkaloids by APCI. For detailed information on the operating conditions of these various applications we refer to the specialized literature in this field.

Application

The applicability of HPLC coupled to photodiode array detection as well as to mass spectrometric detection in the field of forensic sciences will be demonstrated by the analysis of cocaine and some of its metabolites by both techniques. Cocaine, benzoylecgonine and cocaethylene have been determined by HPLC-DAD using 2 mL of blood, serum or urine under reversed-phase gradient conditions. The quantitative limit, defined as that concentration that can be

determined with an acceptable reproducibility ($\leq 6\%$), is 50 ng mL^{-1} for benzoylecgonine and cocaine and 25 ng mL^{-1} for cocaethylene (using 2 mL of body fluid) (Figure 1).

On the other hand, cocaine, benzoylecgonine, ecgonine methylester, ecgonine and norcocaine have been quantified in urine (1 mL) with an LC-MS system based on step-gradient elution of a large (250×7.6 mm) steric exclusion column followed by atmospheric pressure chemical ionization-mass spectrometry. The detection limits (signal-to-noise ratio = 3) under selected ion monitoring (SIM) mode conditions were 320, 200, 200, 20 and 60 ng mL^{-1} for ecgonine, benzoylecgonine, ecgonine methyl ester, cocaine and norcocaine, respectively. Unfortunately, quantitative limits were not reported for this method (Figure 2).

Both systems used solid-phase extraction for sample preparation. Due to their non-UV-absorbing properties ecgonine and ecgonine methyl ester were not detected in the HPLC-DAD system. This system was, however, able to detect and to chromatograph other toxicologically relevant compounds while for the LC-MS system this is not mentioned.

Conclusion and Perspectives

Besides further optimization of both the liquid chromatographic and the spectrometric parts of the described configurations, a great challenge for the future is the automation of those systems. Complete automation of an analytical procedure including online sample pretreatment is always advantageous

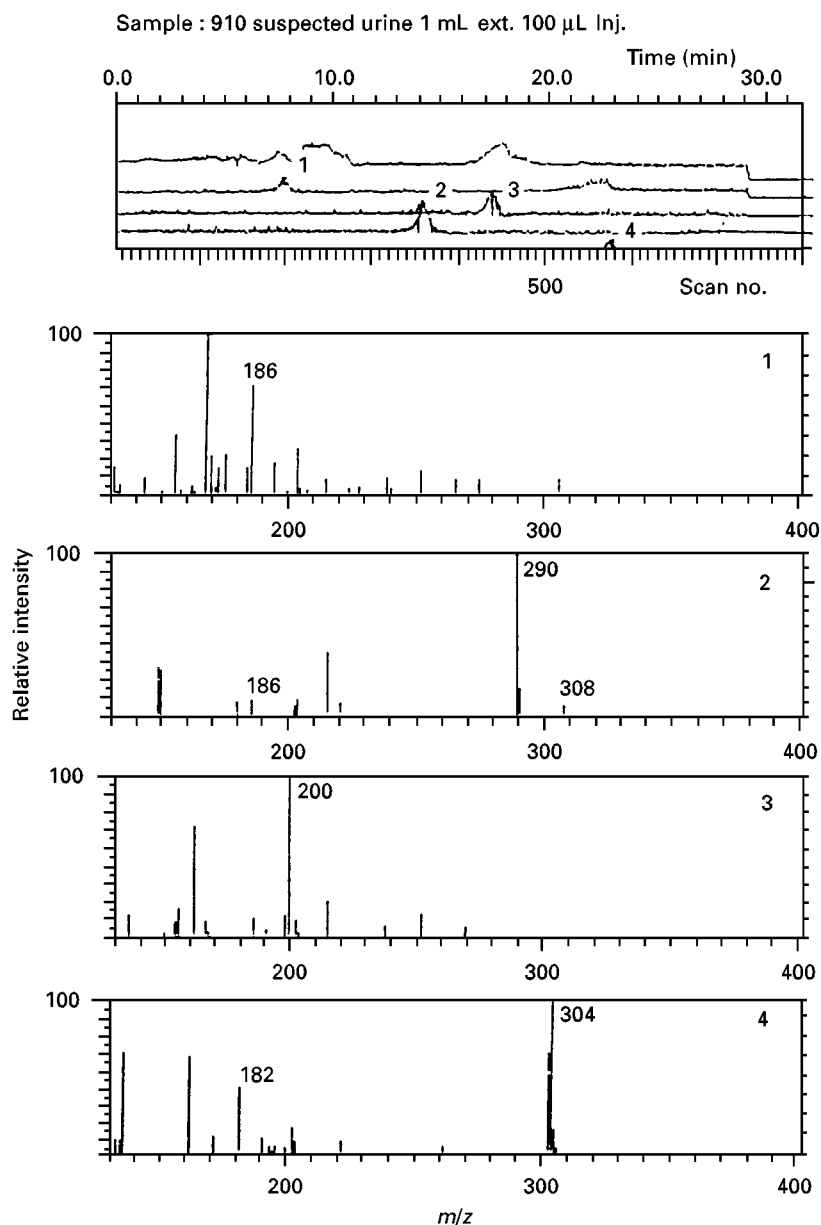

Figure 2 Mass chromatograms and mass spectra of extracts obtained from suspected urine. Peaks. (1) ecgonine; (2) benzoylecgonine; (3) ecgonine methyl ester; (4) cocaine. Levels: (1) 3.2; (2) 4.8; (3) 3.6; and (4) 0.8 $\mu\text{g mL}^{-1}$, respectively. (Reproduced with permission from Nishikawa *et al.*, 1994.)

in STA. Because the optimum performance of HPLC-DAD and more especially of LC-MS are determined by the simultaneous optimization of a large number of interrelated parameters (flow, pressure, temperature, voltage ...), expert systems should be optimized allowing fully automated tuning and control.

The different detection principles as well as the comparable sensitivity demonstrate the complementary character of both HPLC-DAD and LC-MS. In the future, both techniques will undoubtedly gain in

interest and will play an essential function in forensic sciences.

TRACE ELEMENTS BY COPRECIPITATION: EXTRACTION

K. Terada, Kanazawa University, Kanazawa, Japan

Copyright © 2000 Academic Press

In separation by precipitation, contamination with other elements by coprecipitation is undesirable. However, since the publication by Bonner and Kahn of a summary on the separation of carrier-free radioactive tracers by coprecipitation in 1951, this technique has found wider application to the separation and preconcentration of trace elements in various kinds of samples, such as natural water, treated wastewater, high purity metals and geological and biological materials.

In modern textbooks, coprecipitation is recommended for separation and preconcentration of a single trace element or a group of trace elements when the concentration is too low to be directly precipitated or the amount is too small to be handled. In general,

coprecipitation of trace elements is carried out with inorganic and organic precipitants attaining high degrees of concentration, so that subsequent determinations can be performed by using the precipitate itself.

Mechanism

Depending on the nature of the solid phase produced in a solution and the experimental conditions, coprecipitation occurs by different mechanisms. Although the various types of coprecipitation cannot be distinguished clearly, they may be classified according to the following mechanisms: (i) the formation of mixed crystals and mixed chemical compounds, (ii) surface adsorption and the occlusion and (iii) mechanical inclusion of trace components into the other compounds during crystal formation. However, these processes often proceed concurrently, making the precipitation process quite complicated.

Isomorphous Mixed-Crystal Formation

The processes of coprecipitation by isomorphous mixed-crystal formation have been well studied, and the distribution of trace elements is found to be governed by either the Berthelot–Nernst or the Doerner–Hoskins law.

Berthelot–Nernst distribution law (homogeneous distribution). If digestion is continued throughout the precipitation process, equilibrium will be established between the trace elements in the interior of the crystals and the solution, resulting in homogeneous distribution of the trace element in the precipitate. Then, the following equation applies:

$$\frac{(\text{Trace element})_{\text{ppt}}}{(\text{Carrier})_{\text{ppt}}} = D \frac{(\text{Trace element})_{\text{soln}}}{(\text{Carrier})_{\text{soln}}}$$

The higher the value of D , the higher the enrichment of trace elements.

Doerner–Hoskins law (logarithmic distribution)

When the ions cannot reach the interior of the crystals, equilibrium will be established between the trace elements in the solution and those on an extremely thin surface layer of the crystals. This results in logarithmic distribution of the impurities, and the following equation is applicable:

$$\log \frac{T_o}{T_s} = \lambda \cdot \log \frac{C_o}{C_s}$$

where T and C represent trace element and carrier, subscript o and s denote the concentration in the solution before and after the precipitation, respectively.

In practice, coprecipitation of the trace elements may occur between the above two limiting distribution laws.

Surface Adsorption

The surface of a precipitate is particularly reactive. Ions at the surface of a crystal are incompletely coordinated and hence are free to attract other ions of opposite charge from the solution. The surface adsorption of ions on ionic precipitates has been described by the Paneth–Fajans–Hahn rule which demonstrates that adsorption generally increases with the growing surface area of the crystal and with the decrease in solubility of the compounds of the trace elements which the elements form with oppositely charged ions of the crystal. However, there are many exceptions to this rule. For example, in spite of the low solubility of PbCl_2 or PbI_2 , they do not coprecipitate with HgCl_2 or HgI_2 .

Two other factors, the dissociation constant of the adsorbed compounds and the deformation ability of the ions, are important for adsorption. The smaller the dissociation of the adsorbed electrolyte, the larger the adsorptivity. The adsorptivity also increases with increased deformability of the adsorbed electrolyte. The deformability usually increases with the size of the ion.

Another mechanism of adsorption presented by Pauling is an ion exchange process. When the radius of an ion in the solution is similar to an ion on the surface of the crystal, they are exchangeable with each other. This is more effective when an ion in the solution forms slightly soluble compounds with an ion of opposite charge in the crystals. Thus, lead (II) ions can be adsorbed on the surface of a barium sulfate precipitate even in the absence of excess sulfate ion in the solution, according to the following exchange reactions:

Occlusion and Mechanical Inclusion

When an ion adsorbed on a crystal surface from the solution is trapped by subsequent crystal layers, the ion will be occluded in the interior of the precipitate. This situation can be prevented with colloidal precipitates rather than with crystal ones, especially in a rapid precipitation process. For example, freshly precipitated hydroxides or sulfides contain a certain amount of impurities, most of which are released upon ageing of the precipitates. Thus, coprecipitation by occlusion generally gives a poorly reproducible yield of the trace elements to be coprecipitated.

Coprecipitation with Inorganic Precipitants

Coprecipitation of trace elements with inorganic precipitants is usually carried out using colloidal precipitates with a large surface area such as metal hydroxides and sulfides. Among various hydrated oxides, coprecipitation with those of iron(III) and manganese(IV) have been commonly used and are the most studied, but many other hydroxides, such as $\text{Al}(\text{OH})_3$, $\text{Be}(\text{OH})_2$, $\text{La}(\text{OH})_3$, $\text{Th}(\text{OH})_4$ and $\text{Zr}(\text{OH})_4$, and mixtures of metal hydroxides, such as $\text{Fe}(\text{OH})_3$ and $\text{Ti}(\text{OH})_4$, have also been employed.

Coprecipitation techniques are commonly used to separate and concentrate trace elements from very dilute solutions, such as natural water. Since the solubilities of the metal hydroxides or sulfides are mainly governed by the pH value of the solution,

Figure 1 Relation between co-precipitation recoveries of metals with iron(III) hydroxide and pH of the solution.

control of pH is essential for an effective coprecipitation of trace metals. **Figure 1** shows coprecipitation yields of some metal ions with iron(III) hydroxide. It can be seen that removal of many metal ions from a solution may be possible at pH 9–10. However, it should be noted that the coprecipitation yield is also affected by the amounts of precipitants used, the coexisting salts and the ageing time of precipitation. Since most metals form sparingly soluble hydroxides, coprecipitation by hydrated metal oxides is usually of low selectivity, so that different trace metals are likely to be coprecipitated simultaneously.

Three possible mechanisms relating to the adsorption of the trace metal ion on the hydrated metal oxide surface prior to coprecipitation have been suggested.

The first involves ion exchange between adsorbed hydrogen on the hydrated oxide surface and the trace metal ion M in solution according to the equation:

where n is the number of molecules of the hydrated metal oxide and the surface area per molecule is S . M represents the metal cation of charge m . Then the distribution coefficient D is given by:

$$D = \frac{[M]_{\text{surface}} (\text{mol kg}^{-1})}{[M]_{\text{solution}} (\text{mol dm}^{-3})} = \frac{K_n \overline{S_nH^n}}{(H^+)^n}$$

By taking logarithms the equation becomes:

$$\log_{10} D = npH + \log_{10}(K_n) + n\log_{10}(SH).$$

The second postulated mechanism involves the chemical sorption of the trace metal ion M^{m+} on the surface of the hydrated metal oxide, followed by the adsorption of hydroxyl ions:

The third possible mechanism requires the adsorption of hydrolytic complexes of the trace metal ion, rather than the metal ion itself, on the surface of the hydrated metal oxide:

Table 1 shows examples of preconcentration of trace elements by coprecipitation with inorganic precipitants.

Coprecipitation with Organic Collectors

Organic collectors are mainly complexing agents which are sparingly soluble in aqueous solution and form complex compounds with the desired metal ions. The mechanisms of coprecipitation of trace elements with organic collectors have been described by Minczewski *et al.* According to them:

Table 1 Coprecipitation of trace elements with inorganic precipitants

<i>Precipitants</i>	<i>Trace elements</i>	<i>Sample, experimental conditions, comments</i>
Hydroxides		
Al(III)	Cr(III), (VI), Mo, W	Natural waters. Quantitative precipitation: Cr(III) (pH 5–9), Mo (pH 4–5), W (pH 6–8), Cr (VI) (pH 5–6, but it is not quantitative)
	Ce, Eu, La, Lu, Nd, Sm, Tb, Th, Tm, Yb, U	Hot spring and crater waters. 10 mg Al to 2 dm ³ sample. Al precipitation is carried out at near boiling temperature with 14% NH ₃ solution to reach pH 6.5–7.5
	Th, U	Hot spring and crater lake waters. Al ₂ (SO ₄) ₃ (25 mg) is added to 1 dm ³ sample. pH is adjusted to 7–8 with 14% NH ₃ solution
	Li	Geothermal waters: pH should be high (>12.5–13) and a long mixing time is required. The recovery yield is increased by removal of Ca ions and polymerized silica
Be(II)	As	High purity iron steel. Sample (1 g) is digested with HNO ₃ . 5 cm ³ BeSO ₄ (1 mg Be/cm ³) is added in the presence of EDTA (mask matrix elements). As coprecipitates as BeNH ₄ AsO ₄ with Be(OH) ₂ . Perfect recovery is obtained between 1.0 and 3.5 mol L ⁻¹ HCl with relative standard deviation (RSD) of c. 13% for 1.0 µg g ⁻¹ As. Detection limit is 0.3 µg g ⁻¹ of solid sample
	P	High purity iron steel. Same procedure as As. Coprecipitation recovery is 98.7%. Arsenic is removed from the solution as AsBr ₃ for Mo-blue spectrophotometry of P
Bi(III) + In(III)	Co, Cu, Fe, Mg, Ni	High purity Ti metal. 0.5 g sample is dissolved in 6 mol L ⁻¹ HCl (20 cm ³) + HF (0.5 cm ³). Bi(III) and In(III) are added (10 mg and 20 mg, respectively). After addition of 4 cm ³ of H ₂ O ₂ , pH is adjusted to 9.5 with 7.5 mol L ⁻¹ NaOH (pH > 11 for Mg). Ageing time 30–60 min. Perfect recoveries are obtained for all metals. RSD: 0.22%, 0.28%, 2.8%, 0.05% and 0.84%. Detection limit: 0.10, 0.5, 1.8, 0.08, 0.36 µg g ⁻¹ for Co, Cu, Fe, Mg, Ni, respectively
Fe(III)	Cd, Co, Eu	Seawater. Coprecipitation yield in the radionuclide levels: Cd (85% at pH 9.0, Fe 35 mg dm ⁻³), Co (95% at pH 9.0, Fe 35 mg dm ⁻³), Eu (c. 100% at pH 9.0 Fe 10 mg dm ⁻³ , at pH 6.0–9.0, Fe 35 mg dm ⁻³)
	Mo	Seawater. To 500 cm ³ sample, 9 mol L ⁻¹ H ₂ SO ₄ (1.0 cm ³) and 0.1 mol L ⁻¹ FeCl ₃ (3.0 cm ³) are added. c. 96.5% coprecipitation yield of Mo is obtained at pH 4.0; it decreases with increasing pH value
	Cr(III), (VI)	Urine. Cr(III) is found to be precipitated at pH 10, while Cr(VI) remains in the solution. Cr(VI) is only coprecipitated at 4–7
	Cr(III)	Seawater. 4 cm ³ of 2 mol L ⁻¹ HCl, 4 mg Fe(III) are added to 2 dm ³ sample, heat to 50–60°C, 60 cm ³ borate buffer (19.07 g borate + 4 g NaOH in 1 dm ³) is added to solution to pH c. 7.5. Recovery for Cr > 99% at concentration 0.4 µg dm ⁻³ . Precision is ± 0.02 µg dm ⁻³
	As, Cr, Ge, P, Sb, Se, Te, W	Water sample. Optimum pH ranges are 5–7 for Sb and Se, 5–8 for As and W, 5–10 for Cr, Ge and Te, 6–7 for P. Preconcentration factor is 50 for all except Se, where it is only 5
	Cu, Mn, Ni, Pb, Zn	Natural waters. 2 mg Fe(III) is added to 200 cm ³ sample; pH adjusted to 9 (NaOH). Detection limit is c. 1 µg dm ⁻³ . ICP-AES is employed
	Se	Seawater, silicates, marine organisms. 20 mg Fe(III) is added to 5 dm ³ seawater, pH is adjusted to 5–6. After 2 h standing, another 20 mg Fe(III) is added to solution, pH to 4–6 with aq. NH ₃ . RSD is 6.0% for 0.5 µg Se dm ⁻³
	V	Seawater, natural water, biological materials, sediments, rocks. 15 cm ³ 1.0 mol L ⁻¹ HCl and 30 mg Fe(III) are added to 3 dm ³ seawater; pH is adjusted to 5–6 with aq. NH ₃ . Precipitate is dissolved in 10–20 cm ³ 2 mol L ⁻¹ HCl. Coefficients of variation are 2.8% for seawater, 1.3% for silicate rocks, 2.5% for marine plants. Quantitative recovery is attained for 1.8 µg V dm ⁻³
	Ag, Cd, Ce, Cr, Cs, Er, Eu, Gd, La, Mn, Rb, Sr, Yb	Low level waste solution. Effect of pH was studied. Sorption of Cs ⁺ and Rb ⁺ is not strongly pH-dependent, but coprecipitation is low (20%)
	Zn	Quantitative recoveries are obtained for Ag (pH > 8), Cd, Mn, Zn (pH ~ 10), Cr(III) (pH 9–10), Ce, Er, Eu, Gd, La, Yb (pH ~ 10). Sr (pH 11–11.5, 65%). Freshly precipitated Fe(OH) ₃ can be used for the decontamination of radionuclides
	Te	Hair. Sample (2–4 g) is digested with a mixture of HCl + HClO ₄ , heated to evolving fumes, then boiled with 20% HCl to reduce Te to Te(IV). 5 mg Fe(III) is added, pH is adjusted to 9, and centrifuged. Precipitate is dissolved with 3.3 cm ³ conc. HCl, then diluted to 10 cm ³ . Recovery is 96.2 ± 2.4% for 0.2 µg Te

(Continued)

Table 1 *Continued*

<i>Precipitants</i>	<i>Trace elements</i>	<i>Sample, experimental conditions, comments</i>
Hydroxides		
Ga(III)	Al, As, Cd, Co, Cr, Cu, Fe, La, Mn, Ni, Pb, Ti, Y, Zn	Seawater. 5 mg Ga is slowly added to 1 dm ³ seawater. pH is adjusted to 9.0 (NaOH), ageing for 24 h. Precipitate is washed with H ₂ O (remove Na, Mg, K, Ca), dissolved with 2.5 cm ³ 1 mol L ⁻¹ HCl, diluted to 5 cm ³ . 200-fold concentration is achieved. Quantitative recoveries are attained at pH 9.0 for Al, Co, Cr, Cu, Fe, La, Mn, Ni, Ti, Y, Zn. As(III), Cd, Pb (<90%, pH 10)
In(III)	Cu, Fe, Ni	Ti alloy. Sample (0.2 g) is dissolved in HCl, 3 cm ³ H ₂ O ₂ is added to mask Ti. 10 mg In(III) is added, pH is adjusted to 9.0 (NaOH). 100% recoveries at pH 8.5–9.0. Detection limit: Cu 0.8, Fe 8.1, Ni 1.4 µg g ⁻¹ alloy
	Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb	Natural waters. 10 mg In(III) to 100 cm ³ sample. pH to 9.5. Precipitate is separated by centrifuge, dissolved in 1 cm ³ 2.5 mol L ⁻¹ HBr. All are quantitatively coprecipitated. Determination limits for GF-AAS are Cd 0.003, Cu 0.02 µg dm ⁻³
La(III)	As, Bi, Sb, Se, Te	Mo metal. 1 g Mo is dissolved in a mixture of 2 cm ³ conc. HNO ₃ + 6 cm ³ conc. HCl. 50 mg La and small amount filter paper pulp to solution. pH is adjusted to 10.0 (NaOH). After filtration, precipitate is dissolved four times with 2 cm ³ , boiling 6 mol L ⁻¹ HCl. Coprecipitation and dissolution are repeated. Recoveries at pH 10.0, As 96.8, Bi 112.0, Sb 92.4, Se 100.1, Te 106.0% for each 5 µg
	Co, Fe, Mn, Ni, Zn	Seawater. 5 mg La to 1 dm ³ sample, pH adjusted to 9.8 with 1 mol L ⁻¹ Na ₂ CO ₃ . Precipitation at 80°C for 30 min and later aged for several hours
Mn(IV)	Bi, Pb, Sb, Sn	Ni matrix. Ni is dissolved with 25 cm ³ (1 + 1) HNO ₃ , pH adjusted to 2–3 with (1 + 1) aq. NH ₃ . Volume is made up to 200 cm ³ by adding 0.008 mol L ⁻¹ HNO ₃ . MnO ₂ is formed from MnSO ₄ + KMnO ₄ in the presence of acids with 2-min boiling followed by standing for 30 min. Precipitate is treated with 50 cm ³ 10 mol L ⁻¹ HCl. 100% coprecipitation for Bi, Sb, Sn in 6.5 mg Mn precipitated, while Pb in 30 mg Mn, each in 1–100 µg dm ⁻³
	Mo	Seawater, silicates, biological materials. 1.0 dm ³ water is pH adjusted to 2 with dil. HCl. Each 2 cm ³ ethanol and 1 mol L ⁻¹ KMnO ₄ is added and stands overnight. Precipitate is dissolved in saturated aqueous solution of SO ₂ . Quantitative coprecipitation is in the range of pH 1.3–5.5 for Mo level < 5 µg dm ⁻³ seawater
	Ga	Aqueous solution. Coprecipitation conditions are studied. To 200 cm ³ solutions containing Ga (0.5–1000 µg) 5 cm ³ 5% MnSO ₄ is added and adjusted pH to 1.5–1.6 with HCl or H ₂ SO ₄ , to boiling and slowly added 2.5 cm ³ 1.25 mol L ⁻¹ KMnO ₄ , then stands for 5–7 min. Precipitate is dissolved in 10 cm ³ 5% HCl containing 8–10 drops 3% H ₂ O ₂ . Ga is perfectly recovered
	As	Cu, Fe, Ni metals. Sample (0.1–2.0 g) is dissolved in 20–30 cm ³ HNO ₃ (1 + 1). pH to 1.0–2.0 with aq. NH ₃ (except for Fe). As is coprecipitated by adding 60 mg KMnO ₄ + 10 mg Mn(II). Precipitate is dissolved in mixture (HNO ₃ + H ₂ O ₂). Detection limit: 20 ng cm ⁻³
Te(IV)	Se	High salt waste water. After boiling 100 cm ³ of sample (1 mol L ⁻¹ HCl) for 30 min in the presence of 5 g hydrazinium sulfate p.p.b. level Se(IV,VI) is quantitatively coprecipitated with 25–500 µg Te(IV) and completely collected on nitrocellulose membrane filter (pore size 0.2 µm). Heavy metals (high level) do not interfere
	Ag, Au, Pd, Pt, Rh	Cu, Fe, Ni-ores. 1 g sample is dissolved with aqua regia (10 cm ³) at 180°C for 5 h and diluted to 100 cm ³ . 10 cm ³ is evaporated, leached with 0.5 mol L ⁻¹ HCl, Ag is trapped on Dowex 50 w × 8 column and eluted with 0.5 mol L ⁻¹ HCl. Au, Pd, Pt, Rh in 2 mol L ⁻¹ HCl are coprecipitated by adding 5 mg Te (TeCl ₃) and SnCl ₂ (28%)
Th(IV)	Mo	Seawater. To 500 cm ³ seawater (1 cm ³ 9 mol L ⁻¹ H ₂ SO ₄) is added 3–4 cm ³ 0.1 mol L ⁻¹ Th(NO ₃) ₃ , adjusting pH to 6.0 (aq. NH ₃) and standing for 30 min. Precipitate is collected on millipore filter, dissolved in HCl. Precipitation yields: 99.5 (pH 6.0), 81.5 (pH 7.5), 61.6 (pH 8.5)
Zr(IV)	Bi	Sea-, spring-, river waters. To sample ZrOCl ₂ is added, pH to 9.0 with aq. NH ₃ . Precipitate is dissolved in 4 mol L ⁻¹ HCl. Quantitative recovery is obtained at Zr > 10 mg in the pH range 8.8–9.2. > 0.5 mg Al, As(III), Cu, Sn interfere
	Cd, Cu, In, Pb	Sediments. To sample solution containing 0.04 g sediment, 1 cm ³ ZrOCl ₂ is added and pH is adjusted to 8.8. Precipitate is dissolved in 25 cm ³ 4 mol L ⁻¹ HCl. 0.01 µg g ⁻¹ In in sample solution is quantitatively recovered with > 5 mg Zr at pH 8.4–8.8. Cu and Pb are quantitatively collected at pH 8.25–9.0. 0.05 mg As, Bi interfere with Cu determination; 0.05 mg Sn(II), 0.1 mg As(III), Ti(I) interfere with Pb determination. Optimum pH for Cd is 9.0

(Continued)

Table 1 Continued

Precipitants	Trace elements	Sample, experimental conditions, comments
Hydroxides		
	Sb	Seawater, algae, silicates. 1 dm ³ water is added 3 cm ³ 6 mol L ⁻¹ HCl and 300–400 mg K ₂ Cr ₂ O ₇ , heating to 75–85°C for 1 h. After cooling, 150 mg ZrCl ₄ completes dissolution; pH is adjusted to 5.0 ± 0.3, ageing at least 90 min. Recoveries of Sb 99.2% (pH 3.0), 99.1% (pH 5.0), 93.7% (pH 7.5). Standard deviation: 0.003–0.009 µg dm ⁻³ for 0.08–0.42 µg dm ⁻³ Sb
Sulfides		
Bi(III)	As, Sb, Se	Water samples. Coprecipitation is carried out in 1.2 mol L ⁻¹ HCl solution. Minimum amounts: As(III) 10 ng, Sb(III) 50 ng, Se 20 ng
Cd(II)	Cr, Cu, Fe, Mn, Pb, V	BaCl ₂ solution. Coprecipitation conditions are studied for 1 µg of Cr, Fe, Mn, Pb, V, 0.1 µg of Cu. CdS is precipitated from Cd(CH ₃ COO) ₂ with Na ₂ S. Optimum conditions: pH 7–8, BaCl ₂ 15%
In(III)	Co, Cr, Cu, Mn, Zn	Calcite. 0.3 g sample is dissolved with HF, HNO ₃ and HClO ₄ , diluted to 200 cm ³ . 30 mg In is added; pH adjusted to 9.0. In ₂ S ₃ is precipitated by adding 0.1 g thioacetamide. Coprecipitation recoveries: Co 89.4%, Cr 94.5%, Cu 88.8%, Mn 94.9%, Zn 89.1% for each concentration of 25 p.p.m.
Pb(II)	Cu	Tap water, iron and steel. 30 cm ³ tap water is acidified with 0.5 cm ³ 6 mol L ⁻¹ HCl. After adding 1.0 mg Pb, PbS precipitates by passing H ₂ S. Precipitate is dissolved in conc. HCl (1 cm ³). RSD: 0.7% for 5 µg dm ⁻³
Sulfates, phosphates		
Pb(II)	Cr(III)(VI)	Seawater. Na ₂ SO ₄ (0.2 mol L ⁻¹ 8 cm ³) added to 800 cm ³ sample; pH adjusted to 3; 8 cm ³ Pb(NO ₃) ₂ added dropwise. Precipitate filtered on Nuclepore. Cr(VI) only coprecipitates with PbSO ₄ at pH 3. To another 800 cm ³ sample 3 cm ³ 0.2 mol L ⁻¹ Pb(NO ₃) ₂ and 0.2 cm ³ 1 mol L ⁻¹ NH ₄ H ₂ PO ₄ , pH adjusted to > 6 with aq. NH ₃ . Both Cr(III), Cr(VI) are quantitatively coprecipitated with Pb ₃ (PO ₄) ₂ . In seawater, molar ratio of Pb to PO ₄ ³⁻ is kept at 3 for perfect recovery of Cr (VI). 0.08 µg dm ⁻³ Cr is detectable
Bi(III)	Am, Cm, Np, Pu	Sequential separation by coprecipitation with BiPO ₄ , by using suitable oxidizing and reducing agents. Cm(III) is separated from Am, Np, Pu, U in their (VI) valency states by adding K ₂ S ₂ O ₈ -Ag ⁺ before coprecipitation. Next, Am(III) is separated from Np, Pu, U by adding C ₂ H ₅ OH. Pu(IV) is separated from Np and U by adding NaNO ₂ . Last, Np(IV) is coprecipitated by addition of H ₂ O ₂ . Recoveries: Cm (98.5%), Am (97.6%), Pu (94.7%) and Np (96.0%)
Fluorides		
Ca(II)	Cu, Fe	Surface adsorption was shown to be the main cause for coprecipitation. Cu(II) is coprecipitated as counter ion to excess F ⁻ , whereas Fe(III) coprecipitates as FeF ₆ ³⁻ in competition with matrix fluoride
	U	Aqueous solution. To sample 5 cm ³ 1 mol L ⁻¹ Ca(NO ₃) ₂ , 30 cm ³ 0.3 mol L ⁻¹ NH ₄ F solutions are added dropwise. Applicable to coprecipitation of 0.01 ng dm ⁻³ U
	Th	Uranium ore. 1 g sample is digested in 50 cm ³ of mixture (8 mol L ⁻¹ HCl + 0.01 mol L ⁻¹ (NH ₄) ₂ SiF ₆) by heating for 4 h. To solution 10 mg La carrier, HF is added to precipitate LaF ₃ . Precipitate is dissolved with 16 mol L ⁻¹ HNO ₃ . Recovery of ²³⁴ Th tracer is 85% with RSD of ± 12% for 1 p.p.m. level
Oxalates		
Ca(II)	La, Lu, Tb	Biological materials. Substoichiometric precipitation of rare earth elements was studied. To 8 cm ³ of solution containing 0.0125 mol L ⁻¹ Ca(II), 2.0 × 10 ⁻⁷ –6.0 × 10 ⁻⁵ mol L ⁻¹ radioactive RE(III) and 1.25 × 10 ⁻³ mol L ⁻¹ CCl ₃ COOH–0.1 mol L ⁻¹ oxalic acid. At pH 2–5 complete coprecipitation is attained
	Ce, Pm, Sr, Y	Urine. 500 cm ³ is wet-ashed. Resulting salt is treated with 30% H ₂ O ₂ , dissolved in H ₂ O, pH is adjusted to 3.0 (aq. NH ₃). Oxalate is removed by dissolving precipitate in hot HNO ₃ , heating in the presence of 70% HClO ₄ . Residue is treated with H ₂ O ₂ to reduce Ce(IV) to Ce(III) followed by dissolution with H ₂ O. Recoveries: Ce 87%, Pm 89%, Sr 100%, Y 64%

(Continued)

Table 1 *Continued*

<i>Precipitants</i>	<i>Trace elements</i>	<i>Sample, experimental conditions, comments</i>
Salts and metals		
AgCN	Pd	Pure metals. Highly selective for Pd in 10^7 – 10^9 fold excess of Ag, Al, Bi, Cd, Co, Cu, Fe, Mn, Ni, Pb, Sn, Th, Ti, U, Zn. Coprecipitation of Pd is not influenced. Pd is coprecipitated with AgCN. RSD 4–16%; detection limit: $10^{-7}\%$ Pd
As	Se, Te	Geological and biological samples. After digestion of samples by mineral acids ($\text{HNO}_3 + \text{HClO}_4$). Na_3AsO_3 (c. 1.5 mg As) is added. As(III) is reduced to elemental As by phosphorous acid at 80°C for 15 min. Ageing at room temperature for at least 8 h to complete flocculation. Detection limit is 0.1 p.p.m. of Se and Te

1. The sparingly soluble organic compound, such as a bulky organic cation, forms an ion pair with the anionic complex.
2. An insoluble salt formed between the organic anion and the metal cation is coprecipitated together with the excess of the reagent, e.g. metal-8-quinolate in excess of 8-hydroxyquinoline.
3. A soluble chelate compound of a trace metal can be coprecipitated with the precipitate formed between the excess of the reagent and a bulky different organic reagent cation.
4. An inner complex of the metal ion to be separated is coprecipitated with a large excess of the organic reagent such as 1-(2-pyridylazo)-2-naphthol.

Table 2 Coprecipitation of trace elements with organic collectors

<i>Collectors</i>	<i>Trace elements</i>	<i>Samples, experimental conditions, comments</i>
Organic carriers		
α -Benzildioxime (α -BD)	Ni	Seawater. 500 cm ³ samples, 1 mg α -BD, pH \sim 9.5. Ageing time can be minimal. Even 0.2 p.p.b. Ni can be determined
DDTCA (diethyldithiocarbamic acid)	As, Cd, Cu, Fe, Mn, Ni, Pb, Se, Zn	Water samples. Ni, Cu are completely precipitated between pH 1 and 11. Cd, Fe(III), Pb, Zn begin to precipitate at pH 1–2 but complete precipitation is only obtained above pH 4 (pH 5 was used). Complete recovery of As is only obtained at pH 5.0–5.5. For very pure water, metal carrier should be used. Citrate is a powerful masking agent for Fe
	Co, Eu, Mn, Zn	Natural water samples. To 250 cm ³ sample, 20 cm ³ 2% (w/v) NaDDTC solution and 5 cm ³ buffer solution (pH 5) are added. Coprecipitation capacity: 900 $\mu\text{mol L}^{-1}$. Recoveries: Co 97–98%, Eu 88–100%, Mn 85–98%, Zn 82–100%
	Cu, Fe, Hg, Zn	Saline water. To 250 cm ³ sample, 400 mg freshly prepared NaDDTC is added at pH 4.0
DDTCA + dibenzylidene-D-sorbitol (DBS)	As, Cd, Cr, Cu, Fe, Mn, Pb, Sb, Zn	Industrial wastewater, river water. Concentration range 1–50 μg . pH 5.0–5.5 (acetate buffer). 100 mg NaDDTC, 17 mg DBS as flocculant. 94–100% recovery for Mn
Diethylammonium <i>N,N'</i> -DDTC	Cd, Cr, Cu, Hg, Ni, Pb	Drinking, wastewaters. To 500 cm ³ sample is adjusted pH to 5.0–5.5 (acetate buffer), then diethylammonium <i>N,N'</i> -DDTC is added to make 2%. Recovery ranges: Cd 84–94%, Cr 86–102%, Cu 94–106%, Hg 100–108%, Ni 99–110%, Pb 88–92%
DBDTCA (dibenzylthiocarbamic acid)	As(III),(V), Cd, Fe, Zn	Fresh water. pH 2. 100 cm ³ samples, 10 mg of Na-salt of DBDTCA in methanol added. As(III) coprecipitates but not As(V) which precipitates after reduction to As(III) with KI + $\text{Na}_2\text{S}_2\text{O}_3$. Recovery of As(III) 100% in pH range 1–3 but drops drastically for higher pH. 2–3 mg of DBDTCA is sufficient. High recoveries are obtained for Cd, Fe and quite high (87.5%) for Zn
DBDTCA + phenolphthalein	Se(IV)	Fresh water and seawater. 500 cm ³ sample is adjusted to pH 2. 10 mg of Na-salt of DBDTCA and 100 mg phenolphthalein in methanol are added. Without phenolphthalein, recovery is 97% but decreases with ageing time. pH should be < 4 . In the presence of phenolphthalein ageing does not reduce the yield
Dithizone	Ag, Bi, Cd, Cu, Hg, Pb, Pd, Zn	Dilute HCl and HNO_3 solutions. After adjusting acid concentration, 0.1 g ascorbic acid added to reduce Fe(III), finally dithizone is added. Recoveries depend on the acid concentration. (HCl, M, recovery, %) Bi (10^{-2} – 5×10^{-2} , 95), Cd (< 0.002 , 95), Cu (< 2 , 95), Hg (< 1.5 , 95), Pb (< 0.001 , 95), Pd (< 1 , 95), Zn (3×10^{-4} , ~ 40)

(Continued)

Table 2 *Continued*

Collectors	Trace elements	Samples, experimental conditions, comments
Dithizone + phenolphthalein	Ag, Co	Surface water. 4 dm ³ water to be made 0.5 mol L ⁻¹ H ₂ SO ₄ solution; About 28 mg dithizone and 300 mg phenolphthalein are added. Phenolphthalein helps in collecting the precipitate. At pH 1 only Ag is coprecipitated. Co is recovered quantitatively at pH 6.5–8. Dithizone in glacial CH ₃ COOH, phenolphthalein in ethyl alcohol
2-Mercaptobenzimidazole (MBI)	Ag, Au, Hg, Sn, Ta	Seawater. Recoveries were studied at pH 1, 3, 5. To 20 dm ³ seawater (pH 1) 5 g MBI in 100 cm ³ ethanol were added and aged for 2 days (0–5°C). High recoveries are obtained at the following pH ranges: Ag (1–5), Au(1), Hg(1–5) Sn(5), Ta(1–3)
Nioxime (1,2-cyclohexane-diondioxime)	Ni	Aqueous solution. Selective precipitation of Ni at µg level at pH 7.0–9.5. Large amounts of Co, Cu, Fe are masked with Na-tartrate and Ca-EDTA. 32 mg nioxime is used
Oxine (8-hydroxyquinolinol)	Ce, Fe, Pr, Pu	Aqueous solution. Fe was co-crystallized with oxine produced <i>in situ</i> by hydrolysis of 8-acetoxyquinoline. Ce, Pr, Pu also quantitatively recovered
	Cd, Cu, Mn, Pb, Zn	Seawater. The metal ions are quantitatively precipitated in pH range 7.0–8.5 with oxine alone (5 cm ³ of 2% solution) kept at 70°C for 3 h. Detection limits (ng dm ⁻³): Cd 1.4, Cu 10, Mn 5, Pb 10, Zn 6. Recoveries > 98%
	Al	Aqueous solutions. 100 cm ³ sample, pH 6.8–6.9 (0.07 mol L ⁻¹ phosphate buffer). Slow addition of 160 mg oxine. Ageing 1 h. Sensitivity 0.1–0.02 p.p.m.
PAN (1-(2-pyridylazo)-2-naphthol))	Cr(III), Cu, Hg, Mn, Ni, Zn	Seawater. 0.5–4 dm ³ , metal ions are precipitated by adding 20 mg of PAN ethanol solution and heating at 70–80°C for 10 min at pH 6.5–10 for Cu, Ni, Zn; high pH ~10 for Cr(III), Mn. It is preferred that pH should be ~9 in order to decrease coprecipitation of Ca. Alkali and alkaline earth metal ions do not interfere
Organic carriers		
	U	Seawater, tap water, digestate of biological samples. Coprecipitation is most effective at pH 4.5–6.5 with recovery of 85–94%. In the presence of 1,2-cyclohexylenedinitrilo tetra acetic acid (CyDTA) as a masking agent. The method is highly selective for U. Detection limit: 3–4 ng dm ⁻³ for 500 cm ³ samples and 5 µg kg ⁻¹ for 0.5 g biological samples
Thionalide (2-mercapto-N-2-naphthylacetamide) + Oxine	As(III), Cu, Sb(III)(V)	Seawater. 0.005–0.25 mol L ⁻¹ H ₂ SO ₄ . As is only precipitated quantitatively at H ₂ SO ₄ > 0.2 mol L ⁻¹ As(V) is reduced to As(III) by ascorbic acid. 0.015 mol L ⁻¹ H ₂ SO ₄ is used for total As precipitation. 8 cm ³ 2% thionalide in acetone is used. Sb and Cu are coprecipitated with oxine at pH 6–9 while As is not coprecipitated at all
TPAC (tetra-phenylarsonium chloride)	⁹⁶ TcO ₄ ⁻	Aqueous perchlorate solution. Recovery is constant at pH in the range 0.5–13. Precipitation yield is highly affected by TPAC and ClO ₄ ⁻ concentrations. At 25°C, > 90% yields are obtained at TPAC > 0.02 mol L ⁻¹ . Coprecipitation of Tc(IV) is very low
Metal + organic carriers		
Fe (DBDTC) ₃	U	Natural waters. To 500 cm ³ sample. 20 µg Fe(III) and 2 cm ³ 0.1 mol L ⁻¹ KH ₂ PO ₄ (pH 4) are added prior to pH adjustment to 4.0 ± 0.02. DBDTC (1%, 1 cm ³) is added, stirring (15 min), ageing (15 min). Detection limit is 0.4 p.p.b.
Fe (TMDTC) ₃ (tetra-methylenedithiocarbamate)	Cd, Co, Cu, Ni, Pb	Mineral water. 0.5 mg Fe(III) to 200–250 cm ³ sample, pH to 2–3, CO ₂ is boiled out, 50 mg TMDTC is added. The choice of Fe(III) is due to its high concentration in mineral water. High recoveries are obtained > 95%
Co(PDC) ₃ (pyrrolidine dithiocarbamate)	Cd, Cu, Ni	Seawater. 100 cm ³ samples are adjusted to pH 2 (6 mol L ⁻¹ HCl). 50 µg Co (as CoCl ₂), 10 mg APDC are added and aged for 5 min. Precipitate is dissolved in acetone
Pb(PDC) ₂	Co, Cu, Hg	Dead Sea surface water. To 1 dm ³ sample 2.5 mg Pb is added, pH to 3.6, and 20 mg APDC is added. Determination by X-ray fluorescence
Al-oxinate or In-oxinate	Co, Cu, Mo	Agricultural sample digestate. Al-oxinate perfectly recovers Co, Mo, but not Cu. Addition of thionalide or tannic acid or both leads to quantitative recovery for both Al- and In-oxinates. To a 500 cm ³ sample 15 mg Al, 500 mg oxine are added; pH to 4.5; 200 mg tannic acid, 20 mg thionalide
Mg-oxinate	Al, Cd, Co, Cu, Mn, Ni, Pb, Zn Cr(III), Mo, V	Aqueous solutions. To 100 cm ³ solution, 20 mg Mg ²⁺ , 100–200 mg oxine are added at pH 9. Ageing at 70°C for 1 h. Recoveries: 100% except for Cr (83%), Mo (64%), V (70%). Cr recovered at 98% at pH 10.5

5. A chelate of the trace metal is adsorbed and coprecipitated with a water-insoluble organic compound. Several metal dithizonates can be coprecipitated with phenolphthalein.
6. The metal ions are coprecipitated by means of colloidal-chemical sorption on a mixture of insoluble organic reagents.

Typical examples of the coprecipitation of trace metals with organic collectors are listed in **Table 2**.

Synopsis

High performance liquid chromatography (HPLC) has become a useful tool for the analysis of triglycerides from all sources. This article reviews developments for the analysis of molecular species of triglycerides, including stationary phases, mobile phases, sample solvents, detection and identification. It also points out the advantages of silver-ion HPLC and emphasizes the need for stereospecific analysis in the complete determination of triglyceride molecular species because currently this is not possible by reversed-phase HPLC. Finally, the application of HPLC to triglycerides from fats and oils is described.

Introduction

The goal of chromatographic analyses of lipids is the resolution of all classes and molecular species for the purpose of a complete identification and characterization of all the components of a fat or an oil. This characterization is not complete without the

determination of their triglyceride (TG) molecular species profile. Once the fatty acid composition of a determined fat or oil is clear, the knowledge of how these fatty acids are distributed within the glycerol molecule is of major interest.

Fractionation of TGs has been carried out by different chromatographic techniques. Argentation thin-layer chromatography (Ag-TLC) has been employed to separate TG fractions, with subsequent analysis of their fatty acid methyl esters. Direct gas chromatography, using fused-silica capillary columns coated with high-temperature polar stationary phases has also been used for this purpose with rather poor results.

The introduction of chemically bonded phases and high performance liquid chromatography (HPLC) increased the usefulness of liquid chromatography for the separation of TGs. The first paper dealing with the HPLC of triacylglycerols (TGs) was published in 1975 by Pei *et al.* Simple TGs of medium-chain length were separated on a reversed-phase column. Other workers then began to use HPLC for the analysis of long-chain TGs, on silicic acid columns, reversed-phase columns, or both. The first fractionation of natural TGs by HPLC on reversed-phase columns was performed independently in 1977 by Plattner *et al.* and Wada *et al.* The later authors were the first to establish a parameter, termed the partition number (PN; $PN = CN - 2ND$, where CN is the total number of carbons and ND is the number of double bonds in the fatty acids constituting the TG molecule) for

characterizing TG molecules. They found that TGs on reversed-phase columns eluted in increasing order of PN. Today, reversed-phase high performance liquid chromatography (RP-HPLC) is the most frequently employed technique for separating complex mixtures of TGs, as it allows a good resolution of mixtures into molecular species, based on properties such as molecular weight, degree of unsaturation, polarity and molecular configuration. Nevertheless, despite notable success, the progress in RP-HPLC has not been easy, due to difficulties encountered in the process of separation, detection and identification.

One of the main difficulties in the HPLC analysis of TGs is the formation of the so-called 'critical pairs', that is, molecules found to have close behaviour on reversed-phase columns in spite of the difference in chain lengths, number of double bonds and geometrical configuration. Critical pairs, therefore, have been defined as those structures, with the same PN. This problem has not been solved in natural fat analysis yet. However, a long time ago standards of critical pairs of TGs were separated. El-Hamdy and Perkins were able to separate two geometrical isomers: triolein (54 : 3 ccc) from trielaidin (54 : 3 tt), which differ only by the configuration of the double bonds.

The second difficulty is the establishment of a chromatographic system capable of simultaneously resolving TGs with large differences in carbon chain lengths. The separation of short-chain, medium-chain and long-chain TGs in the same chromatogram, involves the utilization of elution gradients and sometimes yields different responses in different parts of the chromatogram.

The third difficulty is the detection of molecules at the column outlet. Refractive index and ultraviolet detectors have been employed, but the analysis of complex mixtures of TGs requires specific detectors. The emergence of the evaporative light-scattering detector (ELSD) and the application of mass spectrometry (MS) to HPLC has been decisive for the analysis of TGs.

The last major problem is the identification of chromatographic peaks. As very few pure standards are commercially available and as many critical pairs remain unresolved, this is one of the most difficult aims to attain. Again, HPLC-MS looks like a useful tool for this purpose, although several authors have developed other systems for TG identification.

Nomenclature

The proposal of Hirshmann has now been universally adopted for structural assignments. An 'sn-' prefix is included in the names of all glycerols. Each fatty acid in the glycerol molecule is identified by listing the sn-1, sn-2 and sn-3 position in order. A 'rac' prefix

indicates that the middle fatty acid in the abbreviation is attached at the sn-2 position, while the remaining two acids are equally divided between the sn-1 and sn-3 positions, yielding a racemic mixture of two enantiomers. A 'β' prefix indicates that the middle fatty acid esterifies the β- or sn-2 position.

Mobile Phase

The selection of the mobile phase is one of the most important factors regarding TG liquid chromatographic analysis. Plattner *et al.* briefly examined the effect of solvent composition upon triglyceride separations. Later, Pauls compared seven binary solvent mixtures for the analysis of olive oil triglycerides. They achieved the best critical pair separation with the use of acetonitrile as weak solvent. *n*-Propionitrile has also been proposed as an eluent but disadvantages include high cost and toxicity. Recently, Hirano and Takahasi have established three factors for the selection of mobile phase solvents in order to obtain optimum column efficiency. Solvents should be low in molecular weight and viscosity but high in solubility of TGs. These factors must be balanced to ensure high column efficiency.

The function of the organic modifier is to improve the solubility of the compounds in the mobile phase, so as to provide changes in their polarity, and thus increase peak selectivity. An increase in the solvent strength of the mobile phase is directly related to an increase in both retention time and resolution of TGs, including critical pairs. Among the organic modifiers tried, Pauls *et al.* showed that chloroform and tetrahydrofuran had the greatest solvent strength for the elution of the critical pair POO-OOO (52 : 2-54 : 3, PN = 48), while the best resolution for the pair LOO-LPO (54 : 4-52 : 3, PN = 46) was achieved with dichloromethane. The dependence of resolution upon solvent composition is a function of the extent to which a solvent can shift retention per double bond compared to the extent to which it shifts retention per carbon unit. The most commonly employed binary solvent mixture for TG analysis is acetone in acetonitrile as the weak solvent. However, acetone is incompatible with UV detectors as it absorbs at the same wavelengths as TGs.

The analysis of TGs by RP-HPLC has been performed for a long time with isocratic elution, due to the general use of refractive index (RI) detection. This system has provided good results for simple oils, but the analysis of complex fat mixtures, i.e. animal fats, requires gradient elution conditions. The goal is to achieve a good resolution for poorly retained TGs (saturated molecular species with short-chain fatty acids) and, at the same time, to elute, in a reasonable

separation time, the most retained TGs (saturated molecular species with long-chain fatty acids). This permits the resolution of complex mixtures of TGs, such as those from fish oils, containing long-chain polyunsaturated fatty acids, and from milk fats, with a broad range of PN values.

Acetone, *n*-propanol, methyl tert-butyl-ether or dichloromethane, give good results when used in gradient conditions with acetonitrile. The gradient systems can be linear or nonlinear. Nonlinear gradients, and step gradients have shown better separations of critical pairs.

Sample Solvent

The sample solvent is of great importance when the sample is a complex mixture of TGs with a wide range of polarity, because it is enormously difficult to find an appropriate solvent for all the TGs. Moreover, the selected solvent must permit an appropriate contact between the solute and the stationary phase for chromatographic separations. Tsimidou and McRae studied the influence of the injection solvent on the RP-HPLC of TGs. They found that chloroform produced inferior resolution under all conditions, which was accentuated by the injection of large vol-

umes. Acetone was recommended, but it is not suitable for high-molecular-weight saturated TGs. Mobile phase has also been suggested as an ideal solvent, but others have employed hexane obtaining better results.

Stationary Phase

Reversed-phase columns are used for separating homologous series of compounds, such as TGs. Previous studies have shown that octadecylsilane (ODS) stationary phases on spherical particles have the best selectivity for TGs, with little variation among the columns of different manufacturers. Columns with a particle size of 3 μm have the highest intrinsic efficiency; however, until recently, their use was restricted because of the high operating pressure needed.

Most RP-HPLC analyses are carried out without column thermostating. However, various workers have shown that an increase in temperature affects retention and selectivity, yielding poorer separations. Although lower temperatures give better separations, elution times are increased significantly. Moreover, highly saturated TGs may precipitate out of the mobile phase. For these reasons, the choice of column temperature must represent a compromise

Figure 1 RP-HPLC of fish oil triglycerides. HPLC conditions: Waters 2690 liquid chromatograph equipped with a Spherisorb ODS-2 column (250 \times 4.6 mm), coupled to a Eurosep DDL-31 light-scattering detector; solvent, a two-step gradient of 20–80% acetone in acetonitrile at flow rate 1 mL min⁻¹.

between good solubility of saturated TGs concomitant with good selectivity of critical pairs.

In 1996, Hirano and Takahashi discussed the theoretical aspects of improving resolution of TG molecular species via RP-HPLC when working at low temperatures. They analysed fish oils (Figure 1), with a low melting point, establishing a critical temperature (-15°C), below which there is no improvement in resolution. Similar results had been obtained before, through lowering temperature only to 15°C .

Detectors

When most separations were made by isocratic elution systems. Refraction index (RI) detection was extensively employed, but complex mixtures of TGs require gradient elution, making RI detection impossible. Moreover, it had low sensitivity and different responses for saturated and highly unsaturated TGs.

The UV detector is compatible with gradient elution and has been used for HPLC analyses of TGs. The absorption region from 200 to 230 nm (ester bond) is used to detect TGs. However, many solvents also absorb at these wavelengths, causing baseline drift with gradient elution systems. In addition, different TGs have nonuniform molar extinction coefficients, and consequently calculation of their response factors with standards is needed for quantitative analysis. Other workers have used flame ionization detection (FID) and attained good sensitivity and baseline stability with elution gradient. Nurmela and Satama tested FID for TGs. They found a variable response for different TGs, although the variation was smaller than with UV detectors. In addition, a nonlinear response of the detector was observed for injections $<5\text{ }\mu\text{g}$. This may be a shortcoming, because only a small portion of the solvent eluted from the column can be introduced into the FID.

The introduction of the mass or evaporative light-scattering detector (ELSD) has brought a major advance in the detection of lipid classes upon HPLC separation. ELSD, being sensitive only to the mass of vaporized analyte, is not limited by the absorption characteristics of the individual components and/or the nature of the eluents. For this reason, it is compatible with gradient elution and volatile solvents do not give baseline drift, as they are removed before detection of the analyte by evaporation. The only requirement is that the compounds to be detected must be much less volatile than the solvent.

ELSD was described for the first time at the end of the 1970s. In 1984, Robinson and Macrae, compared ELSD with UV and RI detectors for the analysis of butter TGs (Figure 2). ELSD provided better

chromatograms, and unlike UV, allowed utilization of acetone. Subsequently, the influence of nebulizer gas pressure, temperature, mobile phase composition and flow rate on the response of the detector was investigated. Regardless of the exponential response of the detector, which depends on solute concentration, nowadays ELSD is the most commonly

Figure 2 RP-HPLC of butter triglycerides. (A) Refractive index detection; Spherisorb-5-ODS-2 and isocratic elution of acetone in acetonitrile. (B) Light-scattering detection: same conditions as (A). employed detector for TG molecular species determination.

Identification of Molecular Species

In spite of their usefulness, all detectors described above have the shortcoming of poor limited structural identification. Mass spectrometry (MS) has become necessary for a complete identification of TG species.

Several methods for mass spectrometry of TGs have been proposed but some drawbacks have been found. Electron impact ionization methods generally result in spectra containing low molecular weight fragments, with no quasimolecular ions present. Electrospray ionization (ESI) provides only quasimolecular ions with no fragmentation. Unfortunately, this lack of fragmentation can result in ambiguity in structural assignments for TGs with identical molecular weight. Information on both the molecular weights and the fatty acyl residues of TGs have been achieved by combination of RP-HPLC and atmospheric pressure chemical ionization MS. Desorption chemical ionization (DCI) and positive ion chemical ionization (PICI) have also been successfully used for TG structural characterization.

When MS is not possible, some authors have used the equivalent carbon number (ECN) for the tentative identification of TGs. The ECN of each TG in the sample is the ECN of the hypothetical saturated TG having the same retention time. When carbon numbers (CNs) are plotted against ECN, straight parallel lines are found for different unsaturated TGs. Thus a theoretical prediction can be achieved, which has become a useful tool for TG identification.

The linear relationship between the retention factor (k) and PN values of the TG, was first established by Wada *et al.* in 1977. Then Herslöf *et al.* estimated theoretically the ECN for unsaturated TGs, on the basis of their relative retention times, from an experimental linear relationship between relative retention time and carbon number. This ECN is analogous to PN ($\text{ECN} = \text{CN} - a'\text{ND}$), with the difference that in this case the value of a' depends on the chromatographic system used for measurements. However, a' generally takes values close to 2 and when $a' = 2$, the values for the ECN and NP are equal. Takahashi *et al.* calculated the value for a' from the relationship between $\log k'$, CN and ND ($\log a' = q + b'\text{CN} + c'\text{ND}$). The value of a' is the quotient between the constants b' and c' . These equations are calculated under isocratic conditions, and are not appropriate for gradient-elution systems. For this reason, some workers have developed new relationships based on the same

parameters, as the equivalent chain length (L) or the theoretical carbon number (TCN).

The chromatographic behaviour of TG molecules in RP-HPLC depends not only on CN and ND but also on the number of unsaturated fatty acids within the molecules (NUFA), because TGs with the same ECN are eluted in the order of the increasing constituent saturated fatty acids. This leads to the equation for ECN ($\text{ECN} = \text{CN} + a_1\text{ND} + a_2\text{NUFA}$).

The TG prediction process becomes increasingly complex when the fat contains a great number of different fatty acids, since the number of possible combinations can be extremely high. Therefore, and as a second part of the prediction process from the ECN, some authors have proposed the application of the equations developed by Takahashi *et al.* These workers developed a matrix model with CN and ND as variables for each fatty acid esterifying the glycerol molecule.

Silver-ion Chromatography

Silver-ion HPLC can be performed on a reversed-phase column (silver ions in the mobile phase), on a silver-loaded, cation-exchange column, or on a silver-loaded silica column. Silver-ion chromatography separates TGs according to their degree of unsaturation, the distribution of double bonds between the fatty acyl residues within a single molecule, the configuration and position of double bonds within each fatty acid and the stereospecific position in which fatty acids are esterified. The mechanism of separation is based on the ability of the π -electrons in the double bonds of the fatty acids to interact with the silver ions of the stationary phase.

Silver ions are incorporated into columns in two different ways: by impregnating the silica-gel support with a silver salt or by bonding silver ions to the phase by means of an ion-exchange phase. The impregnation of columns with silver ions is generally made with silver nitrate in concentrations from 5% to 10%. The problem of short column life is avoided with cation-exchange supports, such as macroreticular sulfonic acid resins or silica-gel supports with chemically bonded methylsulfonic acid groups.

The mobile phase is an important factor affecting the separation of TGs by silver-ion HPLC. However, the nature of the interactions between the silver ions, unsaturated solutes and solvents in the mobile phase has not been fully elucidated. Some workers have suggested using elution gradients combining chlorinated hydrocarbons with acetone and acetonitrile.

Components separated by silver-ion HPLC are commonly detected by evaporative light-scattering detectors (ELSD) or FID, because they place fewer

limitations on the choice of solvents for the mobile phase, but these detectors do not provide structural information on molecular composition. For this reason, mass spectrometry has recently been employed for this purpose.

Christie *et al.* have made the greatest progress in developing silver-ion chromatographic systems. Subsequently, other authors have applied their method for separation of TGs from different natural sources. More useful information of the TG composition of natural fats may be achieved by combining this technique with RP-HPLC. Silver-ion HPLC allows separation of TGs with the same degree of unsaturation; the fractions obtained can then be analysed by RP-HPLC with chain length as a factor for separation.

Stereospecific Analysis

For the complete TG characterization of a fat it is necessary to know not only the fatty acids that constitute a TG molecule but also the positions of attachment. This is of importance because physicochemical properties change depending on the position in which a fatty acid is attached.

However, the stereospecific analysis of a fat is one of the most difficult tasks to undertake, since these molecules are similar in physical and chemical properties. When positions *sn*-1 and *sn*-3 are occupied by distinct acyl groups, the TG molecule will be asymmetric and will have optical activity. However, when the same fatty acid is allocated at both positions, diastereomer forms are outlined. This is not rare, since the main biosynthetic route in animal and plant tissues is the *sn*-glycerol-3-phosphate pathway, and enzymatic systems in this pathway can be specific to certain fatty acids or to certain fatty acid combinations.

Vander Wall and Coleman and Fulton independently developed a theory of fatty acid distribution in the glycerol molecule. They postulated that fatty acids are distributed randomly in the *sn*-2 position and randomly, but independently from *sn*-2, in the *sn*-1 and *sn*-3 positions. They demonstrated that it is possible to know the fatty acid distribution from data obtained on the stereospecific fatty acid composition of the distinct fractions collected after hydrolysis. However, hydrolysis has revealed that fatty acids do not follow a random distribution in TG molecules. In fact, vegetable oils have C₁₈ polyunsaturated fatty acids at the *sn*-2 position, with saturated and C₂₀ and C₂₂ polyunsaturated fatty acids at *sn*-1 and *sn*-3. Oleic acid (C_{18:1}) is distributed at the three positions. Among animal tissues, ample differences can be found. The majority of animal fats have saturated fatty acids at the *sn*-1 position; however, there are

fats like pig adipose tissue, with palmitic acid at *sn*-2, or milk fat, with long-chain saturated fatty acids at the *sn*-1 and *sn*-2 positions.

HPLC analysis, which gives the stereospecific distribution of TGs, uses as substrate mono- and diacylglycerols, obtained after hydrolysis of TGs in the first step of the process. This hydrolysis is usually made through a Grignard reaction with magnesium ethyl bromide. Mono- and diacylglycerols are separated by thin-layer chromatography (TLC) or by solid-phase extraction (SPE). The products obtained may be analysed by liquid-solid chromatography, reversed-phase liquid chromatography or chiral-phase liquid chromatography. By liquid-solid chromatography 1,2-, 1,3- and 2,3-diacylglycerols are separated through formation of (S)-(+)-1-(1-naphthyl)ethyl urethane diastereoisomeric derivatives. The combination of the total fatty acid composition obtained by gas chromatography and liquid-solid chromatography permits calculation of the stereospecific composition of the fatty acids in the TGs of a natural fat.

Reversed-phase chromatography (RP-HPLC) has been less widely employed for this purpose. Sempore and Bezard achieved separations of 3,5-dinitrophenyl urethane (DNFU) derivatives of 1,2- and 2,3-diacylglycerols with a octadecylsiloxane-bonded silica (ODS) column and a mobile phase composed of acetonitrile and acetone. By RP-HPLC Redden *et al.* separated fractions containing all the molecular species of 1,2-, 1,3- and 2,3-diacylglycerol.

Finally, greater success has been achieved using chiral-phase HPLC. Acceptable separations have been obtained for both DNFU derivatives of monoacylglycerols and diacylglycerols employing chiral phases of (S)-2(4-chlorophenyl)isovaleroyl-D-phenylglycine or N-(R)-1-(1-naphthyl)ethylaminocarbonyl-(S)-valine chemically attached to an aminopropylsilane support. However, drawbacks include high retention times and poor resolution. Recently, new chiral stationary phases have been proposed, with (R)-(+)-1-(naphthyl)ethylamine. These phases provide improved resolution and reduction of separation times by using shorter columns. By this method 1,2- and 2,3-diacylglycerols are separated into fractions, which are subsequently analysed by gas chromatography in order to determine their fatty acid composition.

Applications of Triglyceride Analyses by HPLC

Knowledge of the TG profile could be a more appropriate tool to characterize oils and fats, avoiding the

use of saponification and formation of methyl esters. HPLC has become as routine as gas chromatography (GC), providing more complete information about TG composition of fats and oils.

At a research and development level, detailed TG structural information might facilitate understanding of TG biosynthesis in plant and animal cell metabolism, where the activity of acyltransferases are involved. In this regard, knowledge of the TG molecular species of a dietary fat, as well as the TG composition of organs and tissues, can provide significant information for nutritional purposes.

Vegetable Oils

Virgin olive oil presents a characteristic and unique pattern of TGs, which may be used to determine origin and to detect adulteration. Due to its relative simplicity in TG composition and its relevance in human nutrition, HPLC was soon employed in the study of olive oil. In this work, isocratic mobile phases and refractive index detectors were employed. With these conditions, up to 10 TG molecular species could be detected. Triolein (OOO) was found to be the main TG, with the important presence of dioleoyl-linoleoyl-glycerol (LOO) and dioleoyl-palmitoyl-glycerol (POO). Later studies, carried out by RP-HPLC with ELSD, showed that approximately one-half of the total content of TGs corresponds to OOO, while the corresponding percentage of POO is close to 20% and LOO close to 10%. In spite of the improvement achieved, with the utilization of gradient elution systems and ELSD, some critical pairs still remain unresolved.

TG analysis has been extensively employed for the characterization of edible oils. El-Hamdy and Perkins determined the TG composition of olive and soybean oils. The latter oil contained mainly trilinolein (LLL) and dilinoleoyl-oleoyl-glycerol (LLO). Similar results were reported by other authors using isocratic conditions. In the first analysis of soybean oil using gradient elution and ELSD, 19 chromatographic peaks were detected, but could not be identified. A similar number of chromatographic peaks were resolved by Barron *et al.* and Hierro *et al.* using gradients and ELSD. Unexpectedly, LLO was not as abundant as was originally determined; in both studies, LLL was the main TG, followed by LnLO and then LLO. However, Rezanka *et al.* found significant amounts of LLO and low amounts of LLnO by RP-HPLC with MS. These differences might be due to different gradients and mobile phases.

Several other oils of interest have been characterized by HPLC. Perrin and Prevot determined the TG composition of various vegetable oils by gradient

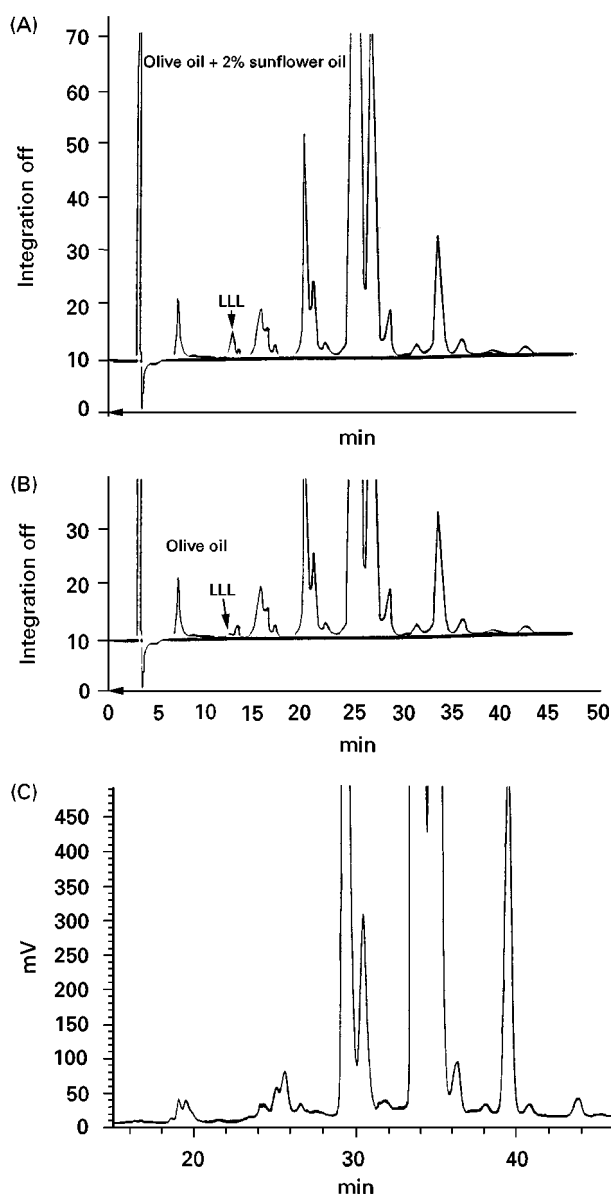

Figure 3 RP-HPLC of virgin olive oil triglycerides. (A) Refractive index detection. Hewlett-Packard HP-1050 liquid chromatograph equipped with a RP-18 column (250 × 4.6 mm), coupled to a Hewlett-Packard HP-1047A refractive index detector; solvent, 50 : 50% acetone in acetonitrile at a flow rate of 0.9 mL min⁻¹. elution RP-HPLC with a light-scattering detector (Figure 3). They analysed oils rich in oleic acid, such as olive and rapeseed oils, oils rich in linoleic acid (soybean and sunflower oils), oils rich in both oleic and linoleic acids (peanut oil) and oil rich in saturated fatty acids (palm oil). They also developed analyses of lard and tallow with great success, identifying more

than 11 chromatographic peaks for each oil or fat. More recently, a newly introduced oleic-rich oil, high oleic sunflower oil, as well as two oils with similar fatty acid composition, borage and primrose oil, have been analysed, each showing a different TG distribution.

Animal Fats

Characterization of animal fats Animal fats are more complex than vegetable oils. The great difference in the fatty acids contained in these fats causes two basic problems. The first one is the difference in chain length and degree of unsaturation, which makes it difficult to achieve a good resolution for all TGs. The second problem is that there is a great number of different fatty acids in animal fats, thus a greater number of TGs appear in the chromatograms, and there are more critical pairs.

Animal fats are employed for industrial purposes. The prediction of the melting behaviour of a fat is difficult due to the complexity of the constituent TGs.

Although the amount of stearic or linoleic acids has been proposed as a good predictor of the consistency of a fat, determination of the TG species provides more information, since not only the fatty acid composition but also the positions in which those fatty acids are esterified, are responsible for its physical behaviour.

Lard is the cheapest animal fat, and commercial shortenings, providing improved physical properties, are usually prepared by its interesterification. Al-Rasheed *et al.* analysed pig lard by RP-HPLC with RI detection to characterize it before and after randomization. Lard has been analysed many times before. Other interest has been focused on pig fat TG characterization to determine the conditions used in pig husbandry.

Because of its complexity, the structural elucidation of milk and butter fat TGs is a formidable task. The large number of fatty acids it contains has made milk fat a particular challenge in terms of TG separation and identification. Until the introduction of ELSD, no satisfactory results had been obtained. The

Figure 4 RP-HPLC of rat liver triglycerides. Two columns (Spherisorb ODS-2 3 μm) connected in series with a nonlinear elution gradient of 20–100% (v/v) acetone in acetonitrile were developed at a rate flow of 1.0 mL min⁻¹. (Reproduced with permission of Perona JS and Ruiz-Gutierrez V. *Journal of Liquid Chromatography and Related Technologies*, in press. Copyright Marcel Dekker.)

first to analyse butter fat by HPLC with ELSD were Robinson and Macrae in 1984; they also compared the chromatograms obtained with those of other detectors, such as UV and RI. As milk fat needs gradient-elution systems, the latter detectors offered poor resolution. FID, with linear and non-linear gradients of acetone in acetonitrile has also been used to give 62 peaks. Resolution was enhanced when ELSD was applied, almost always with acetone in the elution system. Using this method, up to 111 peaks were separated with a nonlinear gradient of acetone–acetonitrile as mobile phase.

Nutritional interest Not only industry is interested in the evaluation of the TG content of foods. Medical and nutritional benefits can be achieved through determination of molecular species of TGs.

Human milk, as well as cow or ewe milk fat, have been subjected to analysis for both industrial and nutritional purposes. The objective is to achieve the substitution of the oils employed at present in milk formulas for infants (coconut oil, corn oil) with others closer in composition to human milk. The TG structure seems to be an important factor for the bioavailability and absorption process of fats in the first weeks of life. It has been suggested that unsaturation of TG fatty acids does not affect pancreatic lipase levels, whereas the chain length of the constituent fatty acids does appear to exert an effect. The distribution of fatty acids within the glycerol molecule might also effect absorption, as it has been shown to regulate TG hydrolysis to 2-monoacylglycerol and fatty acids.

The physiological effects of TG structure and composition of the diet are more relevant in the intestine and liver, the most actively involved tissues in TG synthesis and secretion. The specificity of lipolytic enzymes for fatty acids acylated at the *sn*-1 position of the glycerol molecule affects the re-synthesis of TGs either in enterocytes or hepatocytes. After this re-synthesis, TGs are transported via lipoproteins, to peripheral tissues so that their constituent fatty acids are incorporated into the cellular lipid metabolism. However, until recently little has been done on TG from these tissues or lipoproteins.

Thirty-one molecular species of TG from rat liver have been identified by RP-HPLC with an ELSD by Perona *et al.* (Figure 4). Oleic, linoleic or palmitic acids formed the main TGs in the rat liver. Rat liver had also been investigated for TG molecular species by other workers using ELSD, resolving a lower number of TGs. Yang *et al.* observed that the fatty acid composition and the major molecular species of TG

in the rat liver were very similar to those of TG in very low density lipoproteins (Figure 5). Parreño *et al.* studied plasma TG composition of a Catalonian population by HPLC.

Adipose tissue is the most important extrahepatic tissue in regulating lipid metabolism. Although it contains up to 97% of TGs, little work has been done to study its composition of TG molecular species. Huang *et al.* have reported 18 molecular species of TGs in rat adipose tissue using HPLC with UV detection (Figure 6).

Figure 5 RP-HPLC of rat liver (A) and very low density lipoprotein (B) triglycerides. Conclusion

The chromatographic analysis of TGs has undergone great advances in the last few years. Among other factors, the advent of reversed-phase HPLC and the emergence of the evaporative light-scattering detector (ELSD) allow the resolution of many TG applications in vegetable and animal samples. Nevertheless, the

shortcomings of TG identification need to be improved. Mass spectrometry (MS) is a helpful tool for this purpose. However, it is still difficult for many researchers to incorporate such a technique in their laboratories. The drawback of the incomplete resolution of critical pairs of TGs with the same ECN and the stereo specific analysis of TGs are the two challenges which investigations will have to address in the near future.

Introduction

Triglycerides (TGs) belong to the larger group of natural products called 'lipids'. A lipid is one of a wide range of natural materials that are generally based on fatty acids or closely related compounds, are insoluble in water, but soluble in organic solvents. Lipids that are solid at ambient temperature are termed 'fats' whilst those that are liquids are described as 'oils'. Lipids can be split into two groups; neutral lipids, which include acylglycerols, fatty acids, alcohols and waxes, and polar lipids, which include phospholipids and glycolipids.

TGs make up a major part of the group of neutral lipids and are found in an extensive range of animal and vegetable fats, seed and plant oils. Lipids are present in body organs and fluids. They also find their way into many other food products, e.g. frying oils, salad dressings, margarine, butter, and various other types of spreads.

Fully saturated triacylglyceride. (*n* is usually 16 or 18)

Triacylglyceride with one 'arm' saturated and the other two unsaturated. (Values for *m* and *p* can vary, but is most commonly 7)

Triacylglyceride with all three 'arms' unsaturated

Unsaturated triacylglyceride with two 'arms' di-unsaturated and one mono-unsaturated. (*v* and *w* can vary but usually *p* = 7 and *w* = 4)

Figure 1 Structures of different types of underivatized triacylglycerides.

TGs are fully acylated derivatives of the trihydric alcohol, glycerol. Hence more accurately they should be described 'triacylglycerides', but quite often they are commonly called 'triglycerols' or 'triacylglycerols'. The structure of this group of lipids is shown in **Figure 1**. Each 'arm' of the glyceride is an ester of a fatty acid. This chain can be fully saturated or it can vary in unsaturation. Some natural triacylglycerides have the same three ester groups, e.g. tristearin (18:0), tripalmitin (16:0), triolein (18:1), trilinolein (18:2), and trilinolenin (18:3). More usually the fatty acid esters are different on each glycerol 'backbone' leading to many variations dependent on the number of fatty acids available and on the degree of unsaturation.

Degradation

Triacylglycerides are susceptible to hydrolysis with the resulting products being free fatty acids (FFAs), diacylglycerides (DGs), and monoacylglycerides (MGs). If the fatty acid esters are formed from unsaturated fatty acids, then the susceptibility to oxidation and hydrolytic degradation is increased. Unsaturated triacylglycerides undergo oxidative breakdown involving the formation of free radicals. This process can occur just in the presence of atmospheric oxygen at ambient temperature, although the process will be accelerated by increase in temperature. The primary products are initially allylic hydroperoxides that then undergo a series of complex reactions to form volatile compounds including aldehydes, ketones, alcohols, esters, and short chain fatty acids (see **Figure 2**).

Hydrolytic breakdown normally occurs at elevated temperatures and is often catalysed by enzymes; e.g. lipases. This degradation results in di- and monoacylglycerides and long chain fatty acids (see **Figure 3**).

Thin-Layer Chromatography

Without doubt thin-layer chromatography (TLC) is one of the simplest and most widely employed techniques in the analysis of lipids. Over the past 30 years, planar chromatography on a silica gel matrix has proved to be the most practical method of distinguishing between lipid classes including glycolipids, acylglycerols, phospholipids, sphingolipids, and ether lipids. The continued interest in improving the separation capabilities for lipids using TLC is reflected in the recently published literature.

Figure 2 One possible route for autooxidation of unsaturated lipids. R = carbon chain length linked to the glycerol backbone via a COO linkage, R₁ = a saturated carbon chain. Other degradation routes can occur and result in mixtures of aldehydes, ketones, alcohols, esters, and acids. A route to aldehydes and alcohols is shown.

Normal Phase Separations

Of all the stationary phase adsorbents available, silica gel 60 has proved to be the adsorbent of choice for the rapid separation of triacylglycerides and their

Figure 3 Hydrolytic reaction of a typical triacylglyceride. The reaction is usually catalysed by the presence of lipase. The values of n, m, and p are variable depending on the particular triacylglyceride. In the majority of cases, n = 14 (palmitic) or 16 (oleic), and m and p are 4 and 7, respectively (linoleic).

Table 1 Separation of acylglyceride classes on normal phase silica gel. Mobile phase: n-hexane-diethyl ether-acetic acid (70:30:1, v/v)

TG	0.70
FFA	0.45
1,2-DG	0.26
1,3-DG	0.23
MG	0.05

hydrolysis products, including any hydrolytic damage that may have occurred as a result of lipolysis. Normal phase separations enable the resolution of neutral lipids into TGs, DGs, MGs and FFA. The solvent used is normally a mixture of diethyl ether and hexane, pentane or a low boiling petroleum spirit. The ratio is in the range of 15–30% v/v diethyl ether in the saturated hydrocarbon. A modification with a small amount of formic or acetic acid (about 1%, v/v) helps to improve resolution and is necessary where any organic acids (fatty or otherwise) are suspected as being present in the sample. This aids in suppressing ionization of any FFA. The order of retention on the chromatographic layer of sample components tends to follow the expected adsorption/partition type mechanisms. The triacylglycerides, being the least polar, exhibit the least retention and hence migrate well up towards the solvent front with any sterol esters that may be present in the sample. Perhaps surprisingly these are closely followed by the fatty acids. DGs migrate much more slowly and monoglycerides show only the minimal movement from the origin. One of the interesting features of the normal phase separation of TG is the ability to clearly resolve the 1,3 and 1,2 isomers of DGs that may be present (see Table 1). In order to attain adequate migration of the MG from the origin, the TLC plate can be developed twice with diethyl ether to a solvent distance of 20–30 mm with intermediate drying. This enables sufficient migration of the MG from any more polar lipids on or near the origin. Following this separation step, the standard development can be carried out as before. Sometimes the TG zone on the chromatogram may appear somewhat elongated and even a partial resolution of components may be observed. This is due to the variation in the saturation and fatty acid ester chain length of the TG present.

For densitometric evaluation, silica gel 60 high performance thin-layer chromatography (HPTLC) plates can be used and samples applied using an automated band applicator. After development and detection with an appropriate reagent the chromato-

Table 2 Separation of acylglyceride classes on normal phase silica gel impregnated with 5% w/v sodium carbonate. Mobile phase: diethyl ether–n-hexane–methanol (65:35:3, v/v)

<i>Glyceride</i>	<i>R_F value (approx.)</i>
FFA	0.00
MG	0.18

1,2-DG	0.85
TG	0.98

graphic tracks can be scanned at set wavelengths using a spectrodensitometer. Using external standards on the layer, accurate quantification of the separated components can be obtained.

To a limited extent the enzymic hydrolysis of TG in food products can be followed. Sodium carbonate-impregnated (5%, w/v) silica gel plates are used. Before the sample is applied to the layer, the enzymatic action is terminated by the addition of sodium dodecyl sulfate (SDS). The chromatogram is developed for a very short period (about 1 minute) with diethyl ether–methanol (97:3, v/v), which results in all the acylglycerides migrating with the solvent front and the fatty acids remaining at the origin. A modification to this solvent system; diethyl ether–n-hexane–methanol (65:35:3, v/v) results in a separation of all the various acylglycerides from the fatty acids (see **Table 2**).

Variations on the above mobile phases have been developed depending on the type of separation required and the origin of the sample. **Table 3** lists a number of solvent mixtures that have proved successful for various types of TG separations.

When lipid mixtures prove to be complex, two-dimensional systems can be helpful in resolving the large number of components. Although seldom used, there are instances where two-dimensional TLC has enabled the separation of mixed acylglycerides from steryl esters, methyl esters and fatty acids. Sample components can be resolved using a first development

with n-hexane–diethyl ether (80:20, v/v). This is followed by plate drying and development in the second dimension at 90° to the first using a solvent mixture composed of n-hexane–diethyl ether–methanol (70:20:10, v/v). If more polar lipid components are present, then an alkaline-based solvent mixture is recommended for the development in the first dimension (chloroform–methanol–0.88 ammonia solution–water [65:30:2:2, v/v]) followed by an acid-based one in the second dimension (chloroform–methanol–acetic acid–water [100:15:15:3.5, v/v]).

Other Modifications to Normal Phase Separations

Orthoboric acid Orthoboric acid-impregnated silica gel layers are used in the TLC of TG to prevent acyl migration from the 2 to the 1 or 3 position on the glycerol backbone. The speed of migration is dependent on the acyl moiety. It is therefore important that this effect is prevented from occurring in an analysis of DG and MG. Orthoboric acid does this by weak interaction and complex formation with the free hydroxyl groups on the acylglycerides.

Precoated TLC plates can be impregnated with orthoboric acid (15% w/v) dissolved in water–methanol (25:75, v/v). Either dipping or spraying the plate in the solution gives satisfactory results. The plates are dried after impregnation for 30 minutes at 110°C. Separations can then be performed with methanol–chloroform (3:97, v/v) as solvent.

Silver nitrate Silver nitrate or argentation TLC has been used extensively for the analysis of triacylglycerides. The reason for its popularity is that silver nitrate has a retarding effect on acylglycerides that contain unsaturated fatty acid ester moieties. The silver nitrate forms complexes with varying strength of bonding by interaction with the π double bonds. The more double bonds present, the greater the complexation and the less accessible the double bonds, the less the complexation. Hence, polyunsaturated glycerides and FFA will be more retained than their oligo-

Table 3 Solvent mixtures recommended for the separation of acylglycerides on normal phase silica gel

<i>Acylglycerides</i>	<i>Adsorbent</i>	<i>Mobile phase</i>
TG, DG, MG, FFA (as classes)	Silica gel 60	Diethyl ether–n-hexane–acetic acid (80:19:1, v/v)

TG containing oxygenated fatty acid methyl esters	Silica gel 60	n-Hexane–diethyl ether (30:70, v/v)
TG containing epoxy and hydroxyl fatty acids	Silica gel 60	n-Hexane–diethyl ether (1:1, v/v)

Table 4 Solvent mixtures that have proved satisfactory for the separation of acylglycerides on silica gel impregnated with silver nitrate

Sample containing acylglycerides	Mobile phase
Soybean and fish oils	Diethyl ether–n-hexane (8 : 92, v/v)
Palm oil, lard, beef tallow, cocoa butter and groundnut oil	Chloroform–cyclohexane (1 : 1, v/v)
Lard and cocoa butter	Chloroform–benzene–diethyl ether (70 : 30 : 1.5, v/v)
Triacylglyceride standards	Benzene–diethyl ether (85 : 15, v/v)
Positional isomers of triacylglycerides, lard, and sunflower oil	Chloroform–methanol (99 : 1, v/v)
Orange seed oil	Petroleum ether (40–60°C)–acetone (100 : 7, v/v)

unsaturated counterparts whilst any saturated components remain unaffected. As accessibility of the double bonds also has a bearing on the degree of complexation, *cis* and *trans* isomers can be separated and acylglycerides of fatty acids that only differ in the positional location of the double bond can often be resolved.

Impregnation of silica gel 60 plates can be achieved with silver nitrate (10% w/v) dissolved in water–methanol (15:85 v/v). Precoated TLC and HPTLC plates are dipped in the silver nitrate solution for 10–20 s. After draining, the plates are dried in air under fume extraction and then heated for activation at 80°C for 20 minutes.

Argentation TLC has proved to be of immense importance in a number of research areas including plant-derived oils and confectionery fats. In fact, the technique has been proposed as a method for the determination of 2-oleo-1,3-disaturated triacylglycerides in cocoa butter as a part of the necessary analysis in the manufacture of chocolate. As expected, the separation of triacylglycerides follows the order of the number of double bonds with the least unsaturated being the least retained. However, if the unsaturation is in the 2-position, then there is some hindrance to the formation of the silver complex and some differentiation in the separation between the 2- and 1- or 3-position can be observed. As an example of this, it is possible to separate 2-oleo-1,3-distearin (SOS) and 3-oleo-1,2-distearin (SSO). As the interaction of the silver ion with the 2-position isomer is more sterically hindered, this is the one which is less retained on the layer and hence has the slightly higher R_F value. Of course, not only do TG vary in the amount and position of unsaturation, but also both *cis* and *trans* isomers of the same fatty acid esters occur. Examples of this are *cis*-9-octadecanoic acid (oleic acid) and *trans*-9-octadecanoic acid (elaidic acid). If any *trans* isomers are present, these are less retained than the *cis* isomers. Structurally this would be expected as the *cis* double bond is more accessible to the large silver ion, and hence complexes more readily. The general order of separation starting from the least retained and representing the fatty acid

chains of the TG as 0, 1, 2, or 3 depending on the number of double bonds is: 000, 001, 011, 002, 111, 012, 112, 022, 003, 122, 013, 222, 113, 023, 123, 223, 033, 133, 233, 333.

For the common C_{18} chain, the fatty acid chains would be stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), and linolenic acid (18:3). Whilst C_{18} represents one of the most common chain lengths, shorter and longer chain lengths do occur and this increases the complexity of the problem. Palmitic acid (16:0) occurs more, widely naturally than stearic acid (18:0), being present in almost all vegetable fats, fish oils and milk fats. Fortunately for the analyst, the unsaturated versions of the C_{16} chain such as palmitoleic acid (16:1) are only minor components of seed oils and animal fats and only take on significant proportions in fish oils. Typical solvent mixtures used for the development of silver nitrate chromatograms are given in **Table 4**.

Both symmetrical and unsymmetrical TG are present in lard and cocoa butter and these can be separated effectively with two-dimensional argentation TLC. Unsymmetrical TG occur where the carbon chain on position 1-, 2- or 3- on the glycerol backbone vary in length. Examples of this are: POS (palmitin (16:0), olein (18:1), and stearin (18:0) or PPO (palmitin (16:0), palmitin (16:0), and olein (18:1). The separation is carried out on a dual stationary phase plate. One section of the plate is coated with a thin strip of reversed-phase silica gel, and the rest is coated with a normal phase silica gel. The sample is applied to the reversed-phase strip and the chromatogram developed using acetonitrile–acetone (80:20, v/v) as mobile phase. The normal-phase silica gel portion of the plate is impregnated with silver nitrate and the second dimension development then proceeds with a mobile phase composed of chloroform–benzene–diethyl ether (70:30:1.5, v/v).

Reversed-phase Separations

The resolution of TG on reversed-phase layers is usually noticeably better than that on normal-phase TLC. Although separation of acylglycerides, and FFA

Table 5 Stationary and mobile phase conditions for the separation of acylglycerides and free fatty acids on reversed-phase silica gel plates

Sample containing acylglycerides	Stationary phase	Mobile phase
Most seed oils (e.g. sunflower, olive, rapeseed oils)	HPTLC-silica gel RP18 glass plates	Dichloromethane–acetic acid–acetone (1) (20 : 40 : 50, v/v)
Most seed oils	HPTLC silica gel RP18 glass plates	Chloroform–acetonitrile–acetone (2) (20 : 40 : 50, v/v)
Most seeds oils, DG, MG, and FFA	HPTLC silica gel RP18 glass plates	Dichloromethane–ethyl acetate–methanol–acetic acid (3) (27 : 22 : 38 : 12, v/v)

into respective groups is possible using normal-phase silica gel, reversed-phase layers will resolve individual members of these groups into sharp, often well-defined, zones. However, it is only possible to detect unsaturated acylglycerides and fatty acids on reversed-phase layers. This may initially be viewed as a limiting feature of the technique, but as the separation number even with HPTLC layers in one dimension is rarely more than 20, there is always only a finite length of chromatographic layer available in which the separation can occur. Hence, as the saturated lipids are undetectable, there is more separation capacity available for unsaturated compounds.

The reversed-phase separation of TG has resulted in a method for the identification of fatty oils. The protocol is given in the BP98 appendix XN and the EP97 (2.3.2) and shows a typical chromatogram obtained on HPTLC RP18 layers for a number of seed

oils. The test method acts as an identification for a wide range of oils as each has a TLC ‘fingerprint’ of unsaturated acylglycerides unique to itself. Solvent mixtures that give good separation reproducibility for reversed-phase are given in **Table 5**. Solvent mixtures 1 and 2 are comparable, but solvent mixture 3 gives similar resolution for the TG at lower R_F values and also good resolution for many of the DGs, MGs and FFAs. This solvent mixture therefore has been used effectively for investigations into the deterioration of frying oils. **Figure 4** shows a typical chromatogram of a blended frying oil.

As the separation has occurred almost purely by partition, it is possible to relate the positions on the chromatogram of the acylglycerides to the degree and the position of the unsaturation in the molecule. This then enables the prediction of the position of acylglycerides on the chromatogram and aids in the

Figure 4 Separation of unsaturated acylglycerides and FFA on HPTLC silica gel RP18 glass plates. Mobile phase: dichloromethane–ethyl acetate–methanol–acetic acid (27 : 22 : 38 : 12, v/v). Detection with 1% w/v phosphomolybdic acid in ethanol. Plate heated to 100°C for 5 minutes. Scanned at 700 nm with a spectrodensitometer. Sample: degraded blended frying oil. Peaks 1–5 are triacylglycerides, peaks 6–8 are diacylglycerides, peak 10 is a free fatty acid and peaks 11 and 12 are monoacylglycerides.

identification of unknowns. The acylglycerides are separated according to the equivalent carbon number (ECN). This is defined as:

$$ECN = CN - 2n$$

where CN = carbon number, n = number of double bonds.

However, this does not take into consideration the position of the double bonds. For this reason

in HPLC an adjustment has been made to this equation:

$$ECN = CN - d_1n_1 - d_2n_2 - d_3n_3$$

where n_1 , n_2 , and n_3 are the number of double bonds attributable to oleic, linoleic and linolenic acids, respectively.

The values d_1 , d_2 and d_3 are calculated by means of reference triacylglycerides. They are: $d_1 = 2.60$, $d_2 = 2.35$ and $d_3 = 2.17$.

Figure 5 Separation of unsaturated triacylglycerides on an HPTLC silica gel RP18 layer impregnated with silver nitrate (5% w/v solution). Mobile phase: dichloromethane–ethyl acetate–methanol–water–acetic acid (25 : 20 : 35 : 6 : 6, v/v). Detection with 1% phosphomolybdic acid in ethanol. Plate heated to 130°C for 10 minutes. Scanned at 700 nm with a spectrodensitometer. Sample: Fresh blended frying oil. Peaks 3 and 6 are triolein and trilinolein respectively. Other peaks are other unsaturated triglycerides, sterols, and antioxidants unidentified.

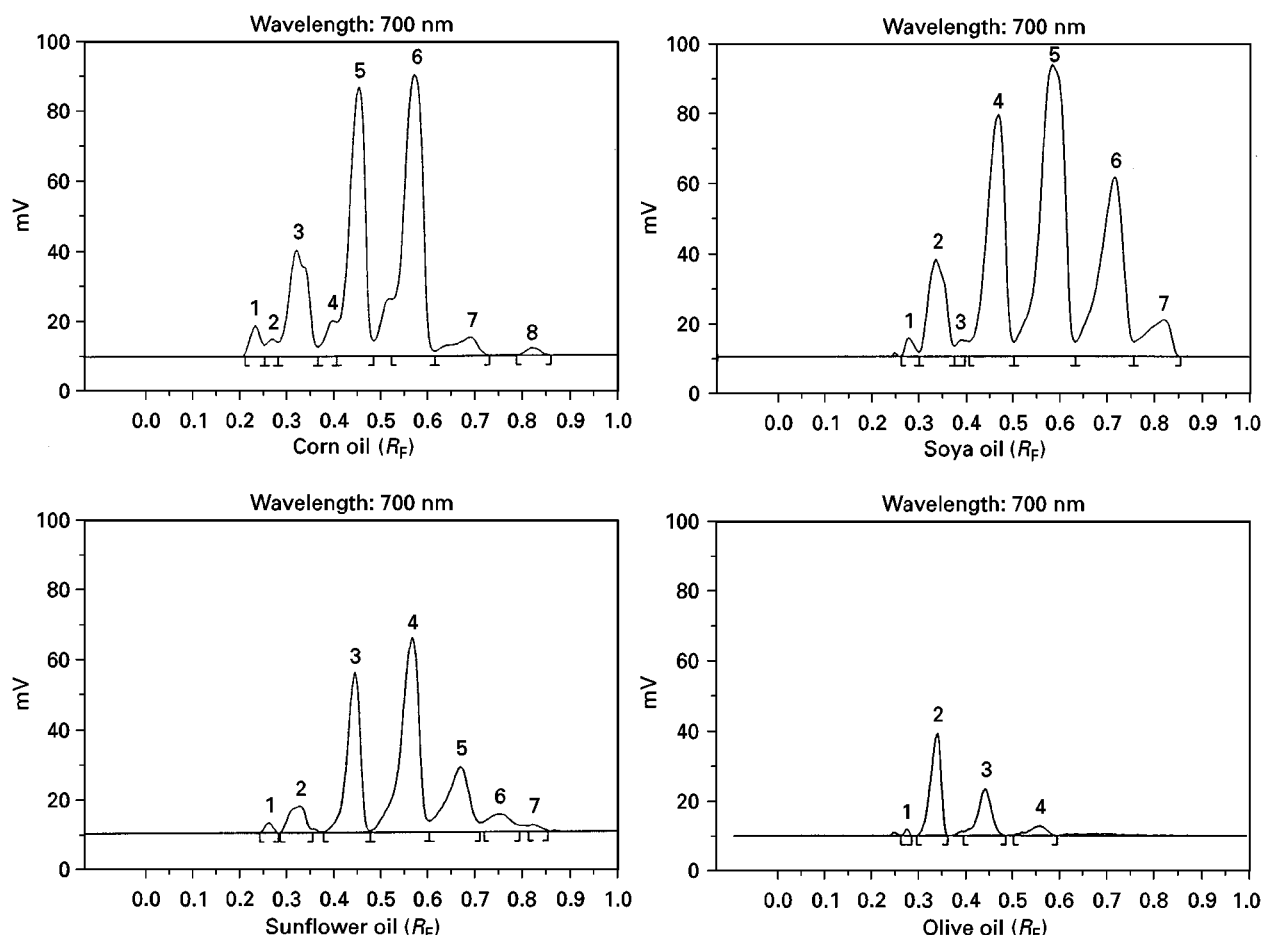

Figure 6 Separation of unsaturated triacylglycerides on an HPTLC silica gel RP18 layer impregnated with silver nitrate (5% w/v solution). Separation conditions as in Figure 5. (Corn oil) Peaks 3 and 6 are triolein and trilinolein respectively. Other peaks not identified. (Soya oil) Peaks 2 and 5 are triolein and trilinolein respectively. Other peaks not identified. (Sunflower oil) Peaks 2 and 4 are triolein and trilinolein respectively. Other peaks not identified. (Olive oil) Peaks 2 and 4 are triolein and trilinolein respectively. Other peaks not identified.

Silver nitrate As with normal phase silica gel, it is possible to modify reversed phase silica gel with silver nitrate. Pre-coated reversed phase silica gel layers can either be impregnated or, where applicable, silver nitrate can be added to the mobile phase. A suitable impregnating reagent can be prepared with silver nitrate (5% w/v) dissolved in water-methanol (10:90, v/v). The separations obtained indicate a much stronger though limited resolving capability than is possible with unmodified reversed-phase layers (see Figure 5). The triacylglycerides are separated over a much wider R_F range enabling more marked differences to be observed in the chromatograms for a number of plant seed oils. A comparison of these is shown in Figure 6. However, as mentioned previously the technique does have limitations. DGs, MGs, and FFAs will all be found at or near the solvent front if the mobile phase has been adjusted to

give maximum resolution for the triacylglycerides. Detection is also not as sensitive as for the corresponding reversed-phase layers (about a four-fold reduction).

Detection Methods

Detection of acylglycerides relies upon the use of chemical reagents as any UV absorbance is weak and none of these neutral lipids show any natural fluorescence (either in the visible or UV spectrum). Most chemical methods rely on reduction or charring techniques for acylglycerides. However, these can still be quite sensitive with the limit of detection usually being in the nanogram range. FFAs are much more reactive and hence a much wider range of detection reagents are available. The same applies to any degradation products due to oxidation where aldehydes, ketones or esters may have formed.

Detection on Normal Phase Layers

Visualization of both saturated and unsaturated acylglycerides is easily achieved on normal phase silica gel layers. However, it should be borne in mind that if the detection reagent is a charring one, then care must be taken when commercial pre-coated plates or sheets are used, particularly with sulfuric acid or chlorosulfonic acid. This is because in order to obtain good reproducibility and abrasive resistance, the pre-coated layers contain a small percentage of a polymeric organic binder. Unfortunately this can also char along with the sample components limiting the contrast between chromatographic zones and the background. However, if the temperature and duration of heating are carefully controlled, good results can be obtained.

Iodine vapour gives very good sensitivity, giving yellow-brown zones on a pale yellow background. The unsaturated compounds are stable for a much longer period of time than the saturated ones. The interaction with the π double bonds forms an iodine complex that is much more stable than the adsorption of iodine by the saturated compounds, which is reversible. These results can be made much more permanent by spraying the plate with soluble starch solution that forms dark blue complexes on the zones where iodine has been adsorbed.

Phosphomolybdic acid reagent (1–5%, w/v solution in ethanol) is probably the most popular reagent for lipid detection and gives a limit of sensitivity of 50–200 ng, depending on the glyceride. Zones appear after heating as blue-grey on a yellow background.

This yellow background can be destained by exposure to ammonia vapour.

Other reagents that have been used to good effect are listed along with the above in Table 6.

Detection on Reversed-phase Layers

Of all the reagents listed in Table 6, the first four can also be used on reversed-phase layers. However, they can only be used to detect unsaturated acylglycerides and FFAs. Sensitivity, however, is on a par with normal phase layers with both iodine vapour and phosphomolybdic acid giving the best results. Charring reagents are best avoided as the background easily chars as well due to the fact that it is bonded with an aliphatic carbon chain.

Detection on Argentation-modified Phases

On commercial pre-coated layers, phosphomolybdic acid gives results comparable with those obtained on normal or reversed-phase plates. There is usually a lack of background staining which improves the contrast. The use of ammonia vapour though is not to be recommended as this reacts with the excess silver nitrate and a brown speckled background appears. For the reversed-phase plates, heating is required at a higher temperature (150°C for 10 minutes) to detect the unsaturated zones.

Some charring techniques have been used for 'home made' normal phase silver nitrate modified layers but these involve the use of very aggressive chemical reagents.

Table 6 Detection reagents suitable for the visualization of acylglycerides and free fatty acids on normal silica gel layers (non-commercial)

<i>Detection reagent</i>	<i>Acylglyceride detected</i>	<i>Observation</i>
Iodine vapour	Both saturated and unsaturated	Yellow/brown zones
Phosphomolybdic acid spray or dip followed by heating at 100–120°C for 10 minutes	Both saturated and unsaturated and FFA	Blue-grey zones on yellow background
Manganese (II) chloride/sulfuric acid [(0.2 g manganese chloride in water (30 mL) – methanol (30 mL) plus sulfuric acid (2 mL)] Heat at 100–120°C for 10 minutes	All acylglycerides and FFA	Brown zones on white background
Copper (II) acetate/sulfuric acid (copper acetate (3% w/v) in phosphoric acid (10% v/v)) Heat at 100–120°C for 10 minutes	All acylglycerides and FFA	Brown-grey zones on a white background
Sulfuric acid (10–20% v/v) Heat at 120–150°C for 15 minutes	Both saturated and unsaturated and FFA	Black or grey zones
Berberine solution (10 mg/100 mL ethanol)	All acylglycerides	Yellow fluorescent zones under UV at 360 nm

Future Developments

It seems unlikely that major developments will occur in the future with improvement of the separation method of acylglycerides on normal and silver nitrate impregnated silica gel. However, the use of the newer commercially available smaller particle size ($\sim 4 \mu\text{m}$) and spherically shaped particles will result in an improvement in resolution, sensitivity and scanned peak shape of chromatographic zones. Automated multiple development (AMD) has already proved to be an excellent analytical tool for focusing zones in lipid separations but is still very much in its infancy with a big potential available for acylglyceride separations.

There is no doubt that reversed-phase HPTLC provides a reliable method for following the breakdown of oils and fats in use. The commercial possibilities here have yet to be fully exploited. There is still much work to be done in developing reliable, but simple, and rapid methods of analysis for triacylglyceride breakdown. Presently available HPTLC procedures not only have the potential to analyse and quantify the total FFA, but also to separate these and determine them individually. Some quantitative work on acylglycerides has already been accomplished, but in the future it should be possible to quantify far more. One of the present drawbacks has been the lack of availability of pure standards, particularly for many of the unsaturated acylglycerides. This is not altogether surprising as many are unstable and need to be kept deep frozen to avoid degradation.

The use of TLC for the analysis of triacylglycerides has further potential in the quantification of other organic species that may be present in oils and fats. Some oils naturally contain tocopherol, which acts as an antioxidant, and other oils may have this, or other antioxidants, added to extend their life. Sterols can also be present. As TLC requires little sample preparation before application to the chromatographic layer, the technique is usually quite easy (and many samples can be analysed at the same time). Many of these other compounds can be separated and determined quantitatively. The future of TLC for the analysis of triacylglycerides shows considerable potential.

ULTRASOUND-ASSISTED METAL EXTRACTIONS

Introduction

Ultrasonic energy has been used for a wide variety of applications in industry, medicine and science. In the analytical chemistry field, most applications lie in the ability of ultrasound to extract compounds from the solid matrix. Solid-liquid extraction with the use of ultrasonic energy (i.e. ultrasound-assisted extraction) has been successfully applied for many years as a sample pretreatment method to extract organic compounds from matrices to which they are weakly bound (e.g. environmental samples). Sonication methods have been compared to other methods for pretreatment of solid samples (e.g. Soxhlet extraction, accelerated solvent extraction and supercritical fluid extraction), being competitive to them owing to its simplicity, efficiency and ease of use. Moreover, sonication methods do not involve the use of high temperatures, pressures or concentrated and harmful chemicals. Usually, ultrasound has been applied to the sample with the use of ultrasonic cleaning baths. Ultrasonic cleaning baths are readily available, large numbers of samples can be simultaneously treated and low-cost instrumentation is involved, but they lack the capability of transmitting sufficient ultrasonic power to produce the desired effects on the sample.

More recently, ultrasound-assisted extraction has been applied to the separation of inorganic compounds and metal ions from the matrix, to facilitate their analytical determination, and to avoid traditional sample pretreatment methods such as dry or wet ashing, which involve tedious and time-consuming treatments with corrosive reagents.

Other application areas of ultrasound-assisted extraction include the selective extraction of different physicochemical forms of elements for speciation. In this case, advantage is taken of the nondestructive character of ultrasound treatments which, under suitable conditions, maintain the integrity of the extracted species.

Finally, ultrasound can accelerate many sequential extraction schemes which are traditionally applied for metal partitioning in environmental samples such as soils, sludges and sediments.

Ultrasound-Assisted Extraction for Metal Determination

Intensive sample pretreatment of biological, environmental and industrial samples is frequently a necessary requirement for elemental analysis, so that ideally a matrix-free solution is obtained. Typically, dry ashing or wet ashing methods involve the use of high temperatures or corrosive reagents, usually under pressure, which demands very stringent safety conditions. However, a simple analyte separation without matrix decomposition is enough for many analytical techniques. Thus, atomic absorption spectrometry (mainly with the use of electrothermal atomization) allows analytical determinations to be carried out with minimum sample pretreatment owing to the low dependence of the analytical signal on the accompanying matrix as compared with other techniques for elemental analysis.

Thus, in the authors' laboratory, a number of elements have been quantitatively extracted from a large variety of matrices when probe-type sonicators operated under optimized conditions are employed. Toxic metals such as Cd and Pb can be easily extracted from mussel tissue and other biological samples, the exact extraction conditions depending on the metal. Cadmium could be quantitatively extracted from a sample mass of 10 mg slurried in a 1.5 mL volume. The sample has to be previously ground, the particle size being a critical parameter in the case of Pb since extraction efficiency diminishes for a particle size large than 150 μm . For Cu and Cd, extraction can be achieved for a particle size larger than 200 μm . The presence of an acidic medium is an essential requirement for quantitative extraction to be attained. For analytical techniques such as electrothermal atomic absorption spectrometry (ETAAS), nitric acid is recommended since unlike hydrochloric acid it does not form volatile compounds with analytes, which are the origin of interferences. In addition, nitric acid combined with the ultrasonic action promotes matrix oxidation so that analyte extraction is facilitated. Minimum acid concentration used for quantitative extraction depends again on the analyte to be extracted. A nitric acid concentration as low as 0.05% v/v is sufficient for quantitative extraction of Cd, whereas Pb requires at least 1% v/v nitric acid. Additional parameters controlling the amount of ultrasonic power delivered to the sample such as sonication time

and vibrational amplitude of the probe (expressed as a percentage of the nominal power) should be optimized for best performance. Metals which are easy to extract, such as Cd, require very short sonication times, typically less than 1 min while stronger bound metals such as Pb require 3–5 min. When using a 100 W probe sonicator, at least a 10% amplitude is necessary for extraction of Cd, while a 60% amplitude is required for Pb. Sample mass is also an important variable; extraction is usually quantitative for a mass of less than 20 mg suspended in 1.5 mL volume. Although the preparation of suspensions in larger volumes with larger amounts of ground material is also feasible, preparation of suspensions in autosampler cups is a more convenient way for ETAAS when sample homogeneity is not a limiting factor. An experimental design applied to the extraction process of Cd and Pb confirmed that soft sonication conditions (minimum sonication time and amplitude) along with maximum particle size (e.g., >200 μm) could be used for quantitative solid-liquid extraction of Cd provided that maximum acid concentration was used (e.g., 3% v/v). On the other hand, Pb needed maximum sonication time, amplitude and acid concentration together with minimum particle size. The concentration of nitric acid proved to be the most critical factor for achieving quantitative extraction.

A study carried out with Pb as target analyte and certified reference materials has shown the importance of using the appropriate ultrasonic processor so that quantitative extraction is attained. Thus, an ultrasonic cleaning bath is not suitable since only a fraction of the analyte is brought into solution even using long sonication times (e.g., 60 min). When comparing two probe-type sonicators (50 versus 100 W), quantitative extraction was observed with the 100 W sonicator for all biological materials attempted. The explanation for the above results could lie in the greater ability of probe-type sonicators to cause cavitation in the liquid medium, which results in a more efficient disruption of solid particles, so facilitating metal extraction.

Incomplete extraction was observed for Pb and Cd from sediments, thereby indicating that matrix-analyte binding plays an important role in the solid-liquid extraction process. This may be due to particle disruption being more difficult with hard materials such as sediments, so that unless the analyte is adsorbed on the surface the fraction of analyte occluded inside the solid particles will not be brought into solution, hence resulting in incomplete extraction.

Usually, the ultrasonic action will cause the matrix to be partly extracted into the liquid medium, but

background absorbance caused by the small amount of matrix released can be easily handled by the background correction system (Table 1).

The use of other analytical techniques for detection after ultrasound-assisted extraction has also been reported. For instance, Ashley has studied the extraction of Pb from several standard reference materials (SRMs) such as lead-based paint, urban particulate and river sediment followed by anodic stripping voltammetry (ASV). Analytical results were satisfactory after ultrasonic extraction for 30 min using a 10% v/v nitric acid solution. ASV has been also used for determination of Pb in workplace air samples collected in the field using cellulose ester membrane filters. The filters were subjected to ultrasound under the conditions given above for SRMs. An advantage of ultrasound-assisted extraction methods over methods involving matrix decomposition (e.g., microwave-assisted digestion) is the ability to use them in the field, hence facilitating on-site analysis with portable instruments.

The use of diluted acids for extraction can also offer a simplified methodology for determination of metals by flame atomic absorption spectrometry (FAAS). In a comparison of five methods for pretreatment of plant samples, Matejovic and Durackova found that extraction of metals could be accomplished with 1 M hydrochloric acid in an ultrasonic bath. After sonication the extracts were filtered so that no particulate material could clog the nebulizer. In this case, the use of a nonoxidizing and complexing

acid such as hydrochloric acid is perhaps more convenient than other acids, since it avoids a final evaporation step to remove the excess of acid as is necessary when concentrated acids are used for mineralization in conventional digestion procedures. Incomplete release of P bound into organic compounds and Fe was observed with this procedure.

Leaching of heavy metals from aquatic plants used as environmental biomonitors has been performed by ultrasound-assisted extraction with a 1% w/w HCl + 15% w/w HNO₃ mixture. In this case, two consecutive extractions were needed to quantitatively extract Mn, Cu and Zn, the recovery of Cu being only about 75%, with RSDs lower than 2.5%. In order to obtain good analytical performance when applying ultrasound-assisted extraction, all the variables influencing the process should be borne in mind: concentration of the suspension (i.e. sample mass and extraction volume), particle size, sonication time, sonication amplitude, type of acid and its concentration, and temperature. This last variable is seldom considered for its influence on ultrasonic extractions. Since most ultrasonic cleaning baths warm up slowly during operation, many applications reported with these devices for extraction use a pre-heated liquid so that temperature is constant, hence improving reproducibility. On the other hand, acoustic cavitation is diminished on increasing the temperature above 50°C, and consequently extraction efficiency is also diminished. Thus, some workers have found only partial extraction for some elements when using a pre-heated ultrasonic bath or allowing the bath to warm up during operation to a temperature higher than 50°C. Other workers have reported quantitative extraction of metals such as Cd, Cu, Pb and Mn from powdered biological samples when sonication is carried out at 40°C. Other extractants successfully employed for solid-liquid extraction with an ultrasonic cleaning bath include dilute HCl, HNO₃ and H₂O₂. Some procedures employing ultrasonic baths for sample pretreatment were aimed at complete digestion of the sample by the use of concentrated acids, and therefore cannot be regarded as extraction procedures.

Applications of Ultrasound-Assisted Extraction for Element Speciation

Ultrasound extraction shows advantageous features for element speciation. Organometallic species can be extracted without changes in their integrity under suitable extraction conditions. Both organic and aqueous extraction media have been used for separation of organometallic and inorganic species from

the solid matrix, most applications using ultrasonic cleaning baths for extraction.

A recent application of ultrasound-assisted extraction with the use of a probe-type sonicator has been reported for mercury speciation in combination with flow injection-cold vapour-atomic absorption spectrometry (FI-CVAAS) for detection. In this case, a 400 mg portion of sample and 1–7 mL of 0.5–7 M acid were placed in a centrifuge tube and sonicated at a fixed ultrasound amplitude for 1–5 min. Selective extraction of methylmercury required less than 5 mL of 2 M HCl, the extraction being quantitative (>95%) when the HCl volume was higher than 2 mL. The extraction could be accomplished using ultrasound amplitude in the range 20–70% for 2–5 min. The optimization procedure was addressed to selectively extract methylmercury from slurried biological samples such as mussel tissue; inorganic mercury extraction required higher HCl concentrations. Both mercury species could be extracted with 5 mL of 5 M HCl and sonicating at 20–70% amplitude for 3–5 min. Methylmercury was determined using sodium tetrahydroborate(III) as reducing agent whereas inorganic mercury was determined by selective reduction with stannous chloride in the extracts containing both species. The limits of detection were 11 and 5 ng g⁻¹ for methylmercury and inorganic mercury, respectively. The repeatability (between-batch precision), was in the range 5–10% for both mercury species.

In a study on As extraction, similar distributions of arsenicals (e.g., arsenobetaine, arsenocholine and dimethylarsinic acid) were found in a comparison between accelerated solvent extraction and sonication. Nonpolar As is extracted with acetone whereas polar As is extracted with 50% w/w methanol.

Cr(VI) has been extracted from industrial hygiene samples with an ultrasonic cleaning bath at 40–50°C for 1 h using alkaline solutions containing 0.05 M (NH₄)₂SO₄–0.05 M NH₃. The Cr(VI) was separated from other cations present in the extract by retention with an anion-exchange resin. Elution of Cr(VI) from the resin was performed with a buffer solution at pH 8. The eluate was acidified with HCl and the complex between Cr(VI) and 1,5-diphenylcarbazide was measured by flow injection-UV/VIS detection. Determination of total Cr following ultrasonic extraction was also feasible using a prior oxidation step with Ce(IV) so that Cr(III) is converted into Cr(VI). This simple and effective preparation method compared favourably with other methods employing intensive treatments leading to matrix decomposition (e.g., acid digestion) for determination of total Cr in fly ash, paint chips, etc.

Sequential Extraction of Metals from Environmental Samples

The bioavailability and mobility of trace metallic and metalloid elements in the environment depend on the chemical form of the element and the type of binding to the matrix. Sequential extraction schemes, although far from being perfect, have the ability to extract elemental species from particular solid phases in sediments, soils and sewage sludge. However, application of these schemes entails a difficult experimental task owing to the large number of slow and tedious stages. For instance, the Tessier scheme apportions metal distribution in four different stages: (1) exchangeable, (2) associated to carbonates, (3) associated to Fe and Mn oxides and (4) associated to organic matter and sulfides. For dissolving a particular solid phase, chemical extractants are applied successively to the solid sample, each follow-up treatment being more drastic in chemical action or different in nature from the previous one. Thus, for

the phases mentioned above, an MgCl_2 solution, an NaOAc solution, an $\text{NH}_2\text{OH}\cdot\text{HCl}$ solution, and an $\text{HNO}_3 + \text{H}_2\text{O}_2$ solution are used sequentially. The Tessier scheme requires an overall operation time of about 18 h. Ultrasonic energy from a probe-type sonicator has been employed for acceleration of the sequential chemical extraction of Cu, Cr, Ni, Pb and Zn from sediment and sewage sludge samples. Conventional and ultrasound-accelerated Tessier extraction schemes offered similar partitioning patterns for the two first fractions (i.e., exchangeable and carbonate-bound) when applied to a sewage sludge sample. However, significant differences in metal extractability were observed for some metals when applying the ultrasound-accelerated Tessier scheme to river sediments. On the other hand, a good agreement for the total extractable contents (i.e., sum of metal contents found in each stage) was seen for Ni, Pb and Zn in sewage sludge and Cr, Ni, Pb and Zn in river sediment, meaning that the ultrasound methodology could be useful for fast screening of extractable

Table 2 Analytical results obtained by applying the conventional and the modified Tessier sequential extraction schemes for metal partitioning in a river sediment and a sewage sludge

metals in solid environmental samples. The operation time per sample was 20 and 28 min for sewage sludge and river sediment, respectively, when ultrasound was used for the Tessier scheme (Table 2).

The sequential extraction scheme, proposed by the Community Bureau of Reference (BCR), now the Standards, Measurement and Testing Programme, consists of three stages: acid-soluble, reducible and oxidizable. The reagents employed are a HOAc solution, an $\text{NH}_2\text{OH}\cdot\text{HCl}$ solution and an H_2O_2 solution, respectively. Despite using a stage less than the Tessier scheme, its operation time is much longer (about 51 h per sample). Application of the BCR scheme to sewage sludge showed that a drastic shortening in time from 51 h to about 22 min per sample could be achieved by the use of ultrasonication. In this case, a much better agreement between the conventional and the ultrasound-accelerated BCR schemes was found in all fractions, so that information concerning extractable metal contents from sewage sludge was virtually the same.

Conclusions

Ultrasound-assisted extraction can be used as an alternative to traditional sample preparation methods for elemental analysis and speciation where matrix separation rather than complete matrix elimination is performed. Sonication methods usually involve mild treatments which meet an important requirement for speciation, i.e., extraction of the species of interest without changes in their integrity. As a result of the decreased amount of matrix released during sonication treatments, matrix interferences can also be reduced. Additionally, ultrasonic treatments provide a significant speeding up of those methods requiring long and tedious extractions (e.g., sequential extraction of metals from solid environmental samples). So far, analytical results obtained on applying ultrasound for sample preparation are very promising, and new developments are expected on the topics addressed in the present work. On-line solid-liquid extraction with the use of ultrasound will require specially designed ultrasonic cells to further simplify sample treatment.

For the analysis of residues of veterinary drugs, liquid chromatography (LC) is of increasing importance: some of these molecules are polar, heat-sensitive and/or difficult to analyse by gas chromatography–mass spectrometry (GC-MS). Moreover, LC is the method of choice for components of high molecular mass. Since the introduction of benchtop LC-MS instruments, there has been an increasing number of publications on the application of this technique in the field of residue analysis.

Equipment

In LC a large variety of packed columns are in use but most residue separations are carried out with some kind of reversed-phase material based on modified silicas (RP-18, RP-8, etc.). Hitherto, in our laboratory, a particle size of 5 µm with column dimensions 150 × 2.1 mm has been commonly used. For a laboratory involved in residue analysis under accreditation, the daily reproducibility of the chromatogram from column to column is very important (see section on quality criteria, below). In the future, column material of smaller particle sizes (3 µm) may be used routinely, allowing faster separation, higher sample throughput and better limits of detection.

The nature of the mobile phase depends on the column used. In most cases a mixture of water and an organic solvent such as methanol or acetonitrile is used. Special LC grades of solvents are necessary. For analysis of residues, gradient elution is a must. In

most cases the column has to be cleaned from interfering components after each run by a gradient. As well as organic solvents, a number of chemicals may be added to the mobile phase (buffers and chelating agents) but the compatibility of these products with the detector should be checked. For LC-MS only volatile components (e.g. trifluoroacetic acid) can be used and this limitation sometimes hinders the transformation of an LC into an LC-MSⁿ method.

Autoinjection is a must for the routine analysis of residues of veterinary drugs, not only for higher sample throughput but also for reproducibility in the validation of the results. However, particular attention should be drawn to the danger of cross-contamination with such injectors, especially in combination with LC-MS which has low detection limits.

Detectors

For screening purposes universal detectors such as UV and light-scattering detectors are used. However, for the confirmation of suspect samples more is required than just retention time and detector response. Since the results of laboratory analysis may have a serious impact on individuals and companies, false positives must be avoided at any price. For example, a sample of poultry feed, analysed by ion chromatography, was suspected to contain KSCN (a thyreostatic drug). Both the retention time and co-chromatography met the quality criteria. However, the presence of KSCN was so unlikely that the effluent was collected and mixed with Fe³⁺ (to give a red colour with SCN). This test was negative. Later on, it was found that the sample contained acetylsalicylic acid, which is often used in poultry rearing, and that the two molecules are not separated in the chromatographic system used.

More analytical evidence could be gathered by using a diode array detector (DAD). However, at low concentrations of the analyte and/or dirty samples, interferences are very likely. With a fluorescence detector more specific analysis at lower detection limits can be performed but in most cases some kind of derivatization of the analyte is needed.

The mass spectrometric detector is very important in residue analysis: the most common interfaces are electrospray (ES) and atmospheric pressure interface (API).

Quantification

Quantitative analysis is necessary for residues of legal veterinary drugs having a maximum residue limit (MRL). The method used must have limit of quantification of (at least) half the MRL. The validation of quantitative method is very time-consuming and expensive. Therefore, qualitative LC is often used for analysis of residues of illegal substances (with a so-called zero tolerance). However, quantitative methods always have a qualitative aspect (a value for the correct substance) while qualitative methods always contain a quantitative background (e.g. the estimation of peak intensities). This quantitative aspect is reflected in the so-called action limits: levels of residues which an efficient laboratory should be able to reach (e.g. 2 p.p.b. for anabolics). In our laboratory, qualitative data (residue present or not) are transferred into quantitative data as follows: a large number of samples (e.g. 50 urines of different origin) are spiked with several anabolics at a certain level (e.g. the action limit) and analysed. The percentages 'detected spikes' are calculated. A 95% detection levels is statistically accepted. So, it could be stated to the inspection services: 'if a sample contains the spiked level, the residue will be detected with a 95% probability'. Higher or lower levels will be detected with higher or lower probabilities. It should also be mentioned that quantification of one signal (e.g. a UV

absorbance) is easier than quantification of a complex signal (e.g. a mass spectrum). However, complex signals give much more information. Internal standards play an important role in quantification in residue analyses. For LC-MS the availability of deuterated standards is often a limiting factor.

Generally, it is important to convince customers (e.g. inspection services) that very reliable quantitative analysis of many samples with low detection limits in a short time for a very low price is not possible.

Special Features of LC

LC-MSⁿ

The first benchtop LC-MS-MS machine based on a modification of an ion trap was introduced in 1996. In tandem MS an ion (e.g. the molecular ion) may be chosen as parent ion, isolated and concentrated in the trap, while all other ions are ejected. Afterwards the speed of the ion is increased: the ion collides with He present in the trap and fragments. The fragment ions (daughter ions) are measured. The daughter ions are theoretically derived from the parent ion only, but in practice some interference is still present (**Figure 1**).

With quadrupoles, MS-MS is normally the end of the story. In an ion trap one daughter ion may be concentrated and fragmented over and over again. In theory, MSⁿ opens the way to a significant reduction of the clean-up of the sample. However, fewer and fewer ions of the analyte are present and the signal-to-noise ratio competes with the ability of the apparatus to detect ions. In practice MS² is only needed for analysis of most residues with LC-MS.

LC as Clean-up in Residue Analysis

Some hyphenated techniques are claimed to be so specific that they only need minimum sample clean-up. In our experience this is not yet true for the analyses of all residues (e.g. anabolics in complex

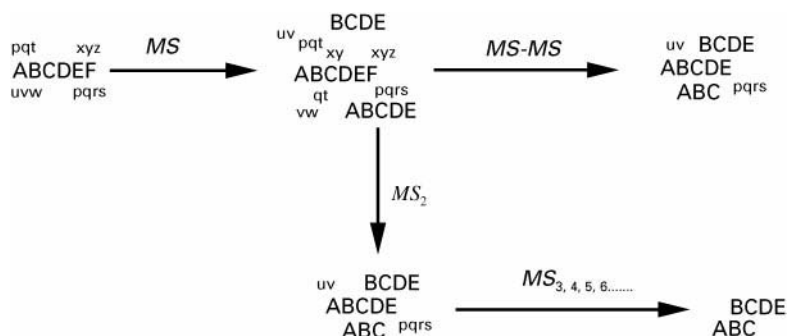

Figure 1 MS (ABCDEF, analyte; pqt, xyz, uvw and pqrs, interferences); MS-MS on ABCDEF; MSⁿ: formation of granddaughter and grandgranddaughter ions.

matrices at the p.p.b. ($\mu\text{g kg}^{-1}$) level). The clean-up of the primary extract needs special attention. LC purification adds a considerable value to the specificity of the method and influences the reliability of the results in a positive sense. By fraction collection, very clean extracts are obtained and the limit of detection is substantially decreased.

Immunological methods can also be coupled to LC to eliminate interfering substances.

Quality Criteria for the Use of LC in Residue Analysis

Minimum quality criteria for the identification of residues using different analytical techniques have been published in the European Commission (EC) directive 93/256. For LC the EC has specified the following quality criteria for methods of analysis which may be used for confirmatory purposes:

1. The analyte should elute at the retention time which is typical for the corresponding standard analyte under the same experimental conditions.
2. The nearest peak maximum in the chromatogram should be separated from the designated analyte peak by at least one full peak width at 10% of the maximum height.
3. The absorption maximum in the spectrum of the analyte should be at the same wavelength as those of the standard analyte within a margin determined by the resolution of the detection system. For diode array detection this is typically within ± 2 nm.
4. The spectrum of the analyte above 220 nm should not be visually different from the spectrum of the standard analyte for those parts of the two spectra with a relative absorbance $\geq 10\%$. This criterion is met when the same maxima are present and no observed point in the difference between the two spectra is more than 10% of the absorbance of the standard analyte.
5. For confirmatory purpose, if the method is not used in combination with other methods, then co-chromatography in the LC step is mandatory.

Discussion of the Quality Criteria

1. Quality criterion 1 is same for any chromatographic procedure: the retention times of the two peaks, formed by the analyte and the standard, should correspond. Otherwise the analyte clearly differs from the standard. A window of 3% is a reasonable quality criterion. Where a great deviation occurs, co-chromatography may be used (see point 5).

2. Criterion 2 requires a resolution of one between two peaks. However, this quality criterion is not clearly described in the EC document. Here the question might be put whether the criterion should only be required for peaks with the same maximum wavelength. For example, an analyte with maximum absorbance of 430 nm may in practice be readily distinguished from an interfering compound with a maximum of 310 nm, even if they partly co-elute. In LC-MSⁿ, this criterion will theoretically not be valid if deuterated standards, which nearly co-elute, are used.
- 3 and 4. These criteria match only LC-DAD. For LC-MSⁿ criteria have not yet been described.
5. In criterion 5, co-chromatography is required for proper identification of an analyte. The usefulness of co-chromatography may be questioned: co-chromatography may prove that the peak in question is not the analyte but not that the peak is without any doubt the analyte. Moreover, it is important that the concentration of standard analyte added is of the same magnitude as that of the sample.

Examples of LC Methods in Residue Analysis

In this section some examples of LC and LC-MSⁿ methods for residues of some illegal growth promoters, legal drugs and feed additives are discussed. More extensive information can be found in the Further Reading section.

LC Methods for Illegal Growth Promoters

Thyrestatic drugs The use of these drugs in cattle results in a spectacular weight gain, arising mainly from an increased filling of the gastrointestinal tract and an augmented water retention. In our laboratory a specific thin-layer chromatography (TLC) method for the determination of thiouracil and analogous compounds has been established. For additional confirmation, the final extract of the TLC method could also be analysed by LC-MSⁿ yielding specific MS² and MS³ spectra (Figure 2).

Anabolic steroids The use of anabolic steroids as growth promoters in the fattening of animals is prohibited in all EU member states. GC-MS is the method of choice for a large number of these components. But some compounds such as stanozolol and its most important metabolite in cattle (16 β -hydroxystanozolol; Figure 3) are difficult.

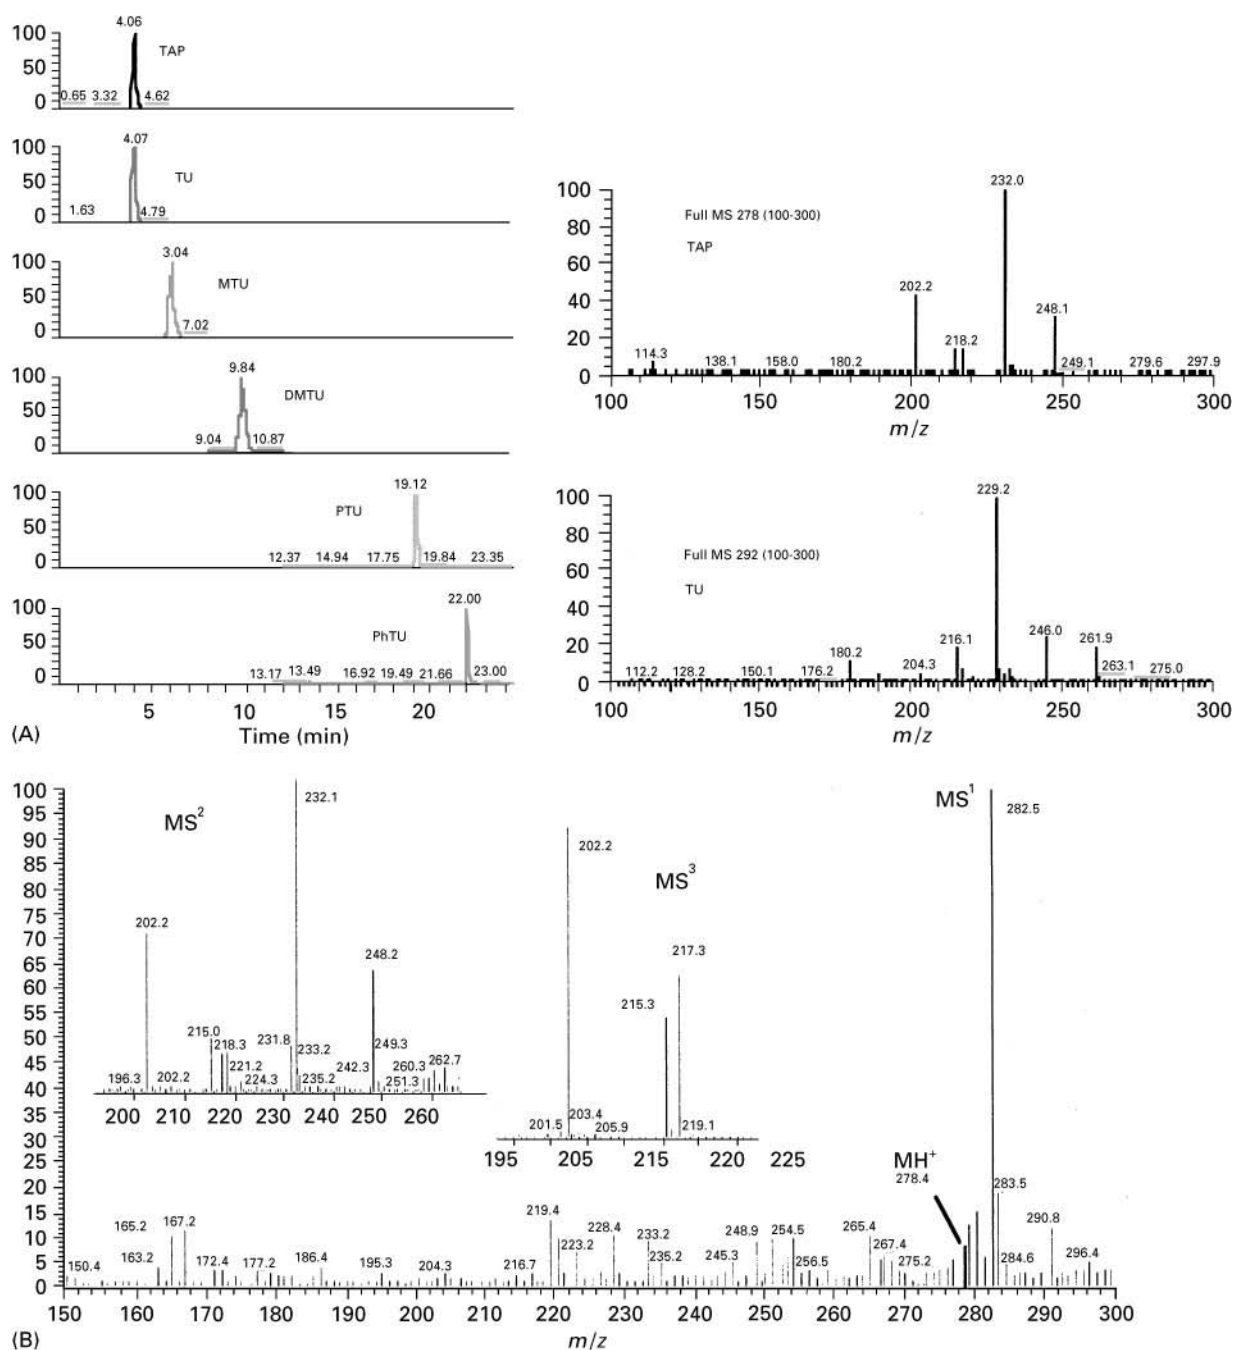

Figure 2 (A) Chromatogram and MS² spectra of some thyreostats. Thyreostats: 4(6)-R-thiouracil (R = H (TU); methyl (MTU); n-propyl (PTU); phenyl (PhTU)); TAP, 1-methyl-2-mercaptoimidazole (tapazole); DMTU, (4(5,6)-dimethyl-2-thiouracil). (B) MS¹, MS² and MS³ spectrum of the thyreostat tapazole.

Recently, GC-MS, LC-MS, MS-MS and MSⁿ methods for this metabolite have been described and compared, in a collaborative study between three Belgian and three Dutch laboratories. It was observed that the spectra obtained on different types of LC-MS systems are clearly different: from one diagnostic ion (in a single quadrupole) to a lot of diagnostic ions

with LC-MSⁿ. This illustrates the difficulty of working out quality criteria for LC-MSⁿ analysis.

β-Agonists During the 1980s the β-agonists found illegal application in animal breeding (extra weight gain together with a repartition between muscle and fatty tissue). An LC method with post-column

Figure 3 16 β -Hydroxystanozolol: the most important metabolite of stanozolol in cattle.

derivatization (with a diazotization mixture) for the determination of clenbuterol and analogues has been described. Later, the very specific detection for anilines was replaced by MSⁿ detection: it is easier to switch from one analyte to another with an LC-MS system than with a post-column derivatization detector. Moreover, deuterated clenbuterol can be used for quantification. In **Figure 4** a chromatogram of some β -agonists (not all are represented here) and an example of an MS² spectrum (tulobuterol) are given.

Corticosteroids Corticosteroids are also abused in cattle fattening. The weight gain is probably due to secondary effects of the corticosteroids, such as water retention. For the analysis of residues of corticosteroids, GC-MS with negative ion chemical ionization (NCI) detection is still the method of choice. However, for the identification of newly used corticosteroids in injection sites, LC-MSⁿ offers more

identification power than GC-MS (no derivatization; different MSⁿ spectra).

Anti-infection Agents

This broad range of chemicals is used for both therapeutic and/or growth-promoting reasons. Screening for residues of antibacterials in slaughtered animals is carried out in most states by microbial inhibition tests on kidney tissue. In the case of a positive test, the identity and (in the case of legal drugs) the concentration of the substance should be determined. It is in this aspect that LC and LC-MS methods are mostly used.

Sulfonamides Several LC methods for the determination of sulfonamides have been described. In our laboratory an LC method from the literature was quickly transformed into an LC-MSⁿ method. In **Figure 5** a chromatogram and MS² spectra of some sulfonamides are given. Currently, six sulfonamides are monitored in one run.

Antibiotics For antibiotics such as penicillins, cephalosporins, quinolones, macrolides and tetracyclines a lot of LC and some LC-MS methods have been described. For tetracyclines, for example, ligands (e.g. oxalic acid) have to be added to the mobile phase to prevent extreme tailing. Post-column derivatization (e.g. with ZrCl₄) followed by fluorescence detection is

Figure 4 Chromatogram of some β -agonists and MS² spectrum of tulobuterol.

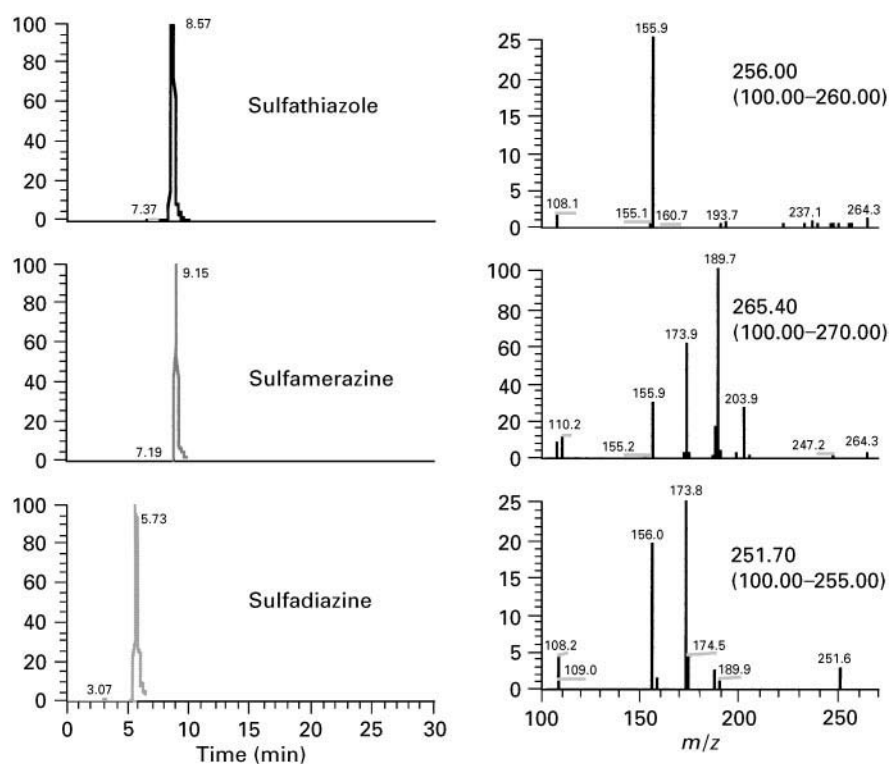

Figure 5 Chromatogram and MS² mass spectra of some sulfonamides.

very specific for these molecules yielding very low limits of detection: 0.5–1.5 $\mu\text{g kg}^{-1}$ in comparison with 2–5 $\mu\text{g kg}^{-1}$ with LC-MS.

Antiparasitic Agents

An example of a potent antiparasitic veterinary drug is ivermectine (a macrocyclic lactone disaccharide).

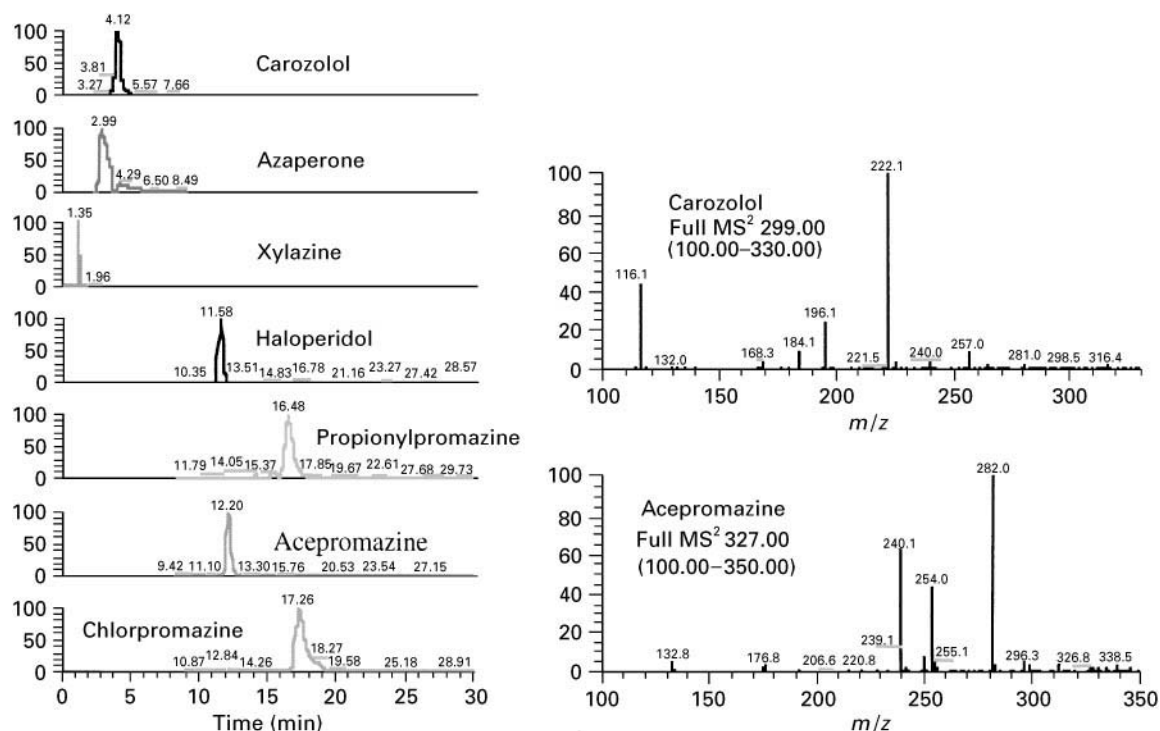

Figure 6 Chromatogram and MS² mass spectra of some tranquilizers.

Figure 7 Formulas of carbadox, olaquinox and metilolaquinox.

The drug is effective in low dosages and therefore requires methods with low detection limits (MRL: $15 \mu\text{g kg}^{-1}$ in porcine liver). Since the molecule has a high molecular mass, LC is the method of choice. HPLC-UV methods for screening of ivermectine residues in animal tissues and milk have been described. For confirmation the molecule can be derivatized (with methylimidazole-acetic anhydride) and analysed by LC with a fluorescence detector.

Tranquillizers

Tranquillizers may be used illegally to prevent stress during the transport of pigs and bulls to the abattoir. A large number of LC methods have been published for the determination of residues of these components. In our laboratory one method was transferred into an LC-MSⁿ method with which seven tranquillizers could be determined in a short time. In **Figure 6** mass chromatograms and the MS² spectra of these components are given. The data, given in Figures 4–6 were obtained with the same apparatus. This is an illustration of the ease of switching from one analyte to another.

Feed Additives

Some components are not considered as veterinary drugs but as feed additives. Examples are the quinoxalines, carbadox and olaquinox. However, residues of these components may be present in edible tissue as well. Also nonregistered equivalents of these components could be used: as an example, the presence of metilolaquinox was suspected in animal feed: this was possibly a modification of olaquinox with a methyl group. LC analysis gave a chromatogram containing a large peak different from carbadox and olaquinox. However, LC-MS analysis gave a molecular mass less than carbadox and olaquinox. By combining MS with NMR a structure for this molecule was proposed (**Figure 7**). This example illustrates the important of MS in residue analysis.

Conclusion

The demands for specificity, reliability, speed and turnover in residue analysis of veterinary drugs are continuously increasing. LC, especially with MS detection, is a reliable analytical technique which should be able to cope with these stringent demands. In comparison with GC and GC-MS, a large range of analytes can be covered and in most cases there is no need for derivatization. It is also easy to switch an LC-MS system from one analyte to another. The lower yield of the LC-MS interfaces and the poorer separation power of LC columns in comparison with GC may be regarded as points to be improved.

The use of illegal alternatives to registered drugs or feed additives poses two important problems for routine inspection: first of all there is no target component. The situation is comparable with the search for a unknown needle in an unknown haystack. Secondly, no analytical standards of the molecule are available. MS (and MSⁿ) is able to give more information about a suspect peak. The future of LC in residue analysis will depend largely on the possibilities of identification of illegal substances abused and qualitative and quantitative analysis of legal veterinary drugs with LC-MSⁿ.

VIRUSES: CENTRIFUGATION

L. L. Bondoc Jr., BioPort Corporation, Lansing, MI, USA

Copyright © 2000 Academic Press

Viruses have proved to be detrimental as well as beneficial. They are notoriously infectious agents that are at the root of several major diseases in man, domesticated animals, and agricultural crops. However, their attenuated or noninfectious forms have been used as vaccines, enabling the development of immunity against particularly devastating diseases. Recently, replication-deficient viruses have been used as agents for gene delivery and as potential vaccine carriers, as they have evolved efficient mechanisms of infectivity.

Viruses are particulate in nature and are made up essentially of DNA or RNA, wrapped in a predominantly protein coat. They range in size from 20 to 2000 nm (0.02–2 μm) and in molecular weight from 4×10^6 to 2×10^9 Da. Many viruses possess an envelope that is typically derived from the host cellular membrane.

Initial isolation of viruses usually involves centrifugation, particularly density gradient centrifugation (DGC). For almost half a century DGC has been regarded as the most rapid, and reliable preparative procedure for the isolation of highly purified and concentrated virus preparations for subsequent physicochemical and biological characterization. As such, it is used as a benchmark against which alternative methods can be evaluated. To date the technique has permitted the isolation and subsequent characterization of a plethora of viruses belonging to at least 39 major families.

Centrifugal Separations

Although significant improvements in centrifugation hardware have led to increased operational efficien-

cies, the theory behind centrifugation and the variations of the technique as applied to viruses are well characterized. In a suspension of particles, the rate at which particles sediment when subjected to a centrifugal force depends on the nature of the particles, the nature of the medium, and the magnitude of the centrifugal force. For spherical particles, the sedimentation rate or velocity of the particle depends on a variety of factors as indicated in eqn [1], one of the many forms of the Svedberg equation:

$$dr/dt = [2r_p^2(\rho_p - \rho_m)\omega^2 r]/9\eta \quad [1]$$

where dr/dt is the velocity of the particle; r_p is the radius of the spherical particle; ρ_p is the density of the particle; ρ_m is the density of the medium; ω is the angular velocity; r is the radial distance of the particle from the axis of rotation; the product $\omega^2 r$ is proportional to the centrifugal force; and η is the viscosity of the medium. It is possible to define a particle in terms of its behaviour in a centrifugal field by manipulation of eqn [1] to yield a simplified version of the Svedberg equation (eqn [2]) that uses the sedimentation coefficient, s , where:

$$s = (dr/dt)/\omega^2 r \quad [2]$$

For most biological macromolecules, the magnitude of s is about 10^{-13} s, so this value is used as the unit of sedimentation, the Svedberg (S). The sedimentation coefficient for viruses varies between 40 and 4500 S, while for globular proteins it is 2–5 S.

Types of Separations

For a particular viral preparation, the most effective centrifugal separation procedure is one that yields a concentrate with significant recovery of bioactivity

and high quality based on several measures of purity. There are three types of centrifugal separations available for viruses: (1) differential centrifugation; (2) rate-zonal centrifugation; and (3) DGC or isopycnic centrifugation. Differential centrifugation separates particles according to size as well as density (from eqn [1]), since denser particles will form pellets at a faster rate than less dense particles of the same mass. By choosing an appropriate centrifugal force and centrifugation time, it is possible to clarify a viral suspension from contaminating fermentation debris by first pelleting the contaminants at a given g force and leaving the virus in suspension, then pelleting the virus at a higher g force. Viruses that are unstable when pelleted can be sedimented on a cushion or plug of material (e.g. caesium chloride, sucrose, potassium tartrate, Nycodenz (Nyegaard & Co.), and glycerol) that has a density higher than that of the viral particles. The major problems with this mode of separation are the low yields and low resolution from contaminants. Differential pelleting is often used for the initial processing of heterogeneous mixtures, to obtain fractions that are enriched in the virus particles of interest prior to further purification.

In rate-zonal centrifugation particles move at different rates depending upon their mass. To avoid the co-sedimentation of particles of different sizes, samples are typically layered as a narrow zone on top of a density gradient. The gradient is used to facilitate the layering of the sample and to minimize convection currents in the liquid column during centrifugation that would otherwise disrupt the particle zones as they move down the tube. Rate-zonal separations are ideal for particles of uniform size but not for particles of the same type that are heterogeneous in size. Furthermore, even though separation conditions can be optimized, it is not yet possible to recover the separated fractions as fractionated species. For viral preparations this mode of centrifugation is primarily used for characterizations, such as molecular weight determination and the determination of possible interactions with other molecules.

The most common method of centrifugal separation for viruses is DGC, or isopycnic centrifugation. In this process the particles move until their density is the same as that of the surrounding medium. The particles are separated purely on the basis of their density, and their size only affects the rate at which they reach their isopycnic positions. Because the separation is an equilibrium process, run times are generally much longer than for rate-zonal or differential centrifugation. Prolonged centrifugation does not affect the separation as long as the gradient remains stable and the activity and integrity of the particles

are not adversely affected by centrifugation. Materials are typically spun at 25 000–200 000 g for up to 20 h. Samples are loaded either on a pre-formed gradient or on self-forming gradient media.

Centrifugation Media

For isopycnic separations, the choice of media is important. There are several desirable characteristics for a medium, the most important being that the maximum density of the gradient is greater than that of the particles to be separated. In general viruses have buoyant densities in the range 1.1–1.5 g cm^{-3} . However, as a result of different levels of hydration of viral particles in different media, the densities of the particles can vary depending on the medium being used. The physico-chemical properties of the solutions of the gradient medium should be known, and it should be possible to determine the precise concentration of the medium using one or more of these properties (e.g. refractive index or densitometry). The medium should be inert and safe to use, and should not interfere with monitoring of the zones of fractionated material within the gradient (e.g. by ultraviolet or visible absorbance, radioactivity counting, protein determination, etc.). It should be easy to separate the sample material from the gradient medium (by dialysis, ultrafiltration, or centrifugation) without loss of the sample or sample activity. Ideally the medium should also form solutions of low ionic strength with low viscosity and be iso-osmotic with the virus.

Gradient media for DGC are either ionic or nonionic. Commonly used ionic media include caesium salts (e.g. caesium chloride), potassium salts, rubidium salts and sodium salts (e.g. sodium chloride). These materials are used to form solutions with maximum buoyant densities of 1.4–2.6 g mL^{-1} . Gradients of caesium salts, especially caesium chloride, are used almost exclusively for virus purification. They can be pre-formed using any of the standard techniques or they can be formed *in situ* by centrifugation. Solutions containing caesium salts are highly ionic, and while they are nonviscous, they all have high osmolarities. Gradients formed from these salts, differ with respect to their solubility, maximum density, activity and steepness, all of which can affect the banding of materials.

Nonionic gradient media can be subdivided into carbohydrates, iodinated gradient solutes, colloidal silica suspensions and proteins. Sucrose, a disaccharide, has been widely used for the isopycnic fractionation of viruses. Its popularity is due to its inertness towards biological materials, ready availability, low cost, and stability. The main disadvantages of sucrose

include its high osmotic strength, high viscosity, hypertonicity for solutions more concentrated than 9% (w/v) and rather low buoyant density of 1.03 g mL^{-1} . Sucrose gradients must be pre-formed for isopycnic fractionations.

To circumvent the problems that arise from fractionating osmotically sensitive particles in high osmotic strength sucrose solutions, several polysaccharides have been used as gradient media. These include glycogen, dextrans, and Ficoll (Pharmacia). Ficoll is produced by the chemical copolymerization of sucrose molecules with epichlorohydrin to give a polymer with a molecular weight of 400 kDa. Ficoll solutions below 20% (w/v), equivalent to a buoyant density of 1.07 g cm^{-3} , have a relatively low osmolarity, although at higher concentrations the osmolarity rises sharply. Gradients of Ficoll, which have a higher viscosity and better stability than sucrose gradients, must be prepared using a gradient mixer.

Most iodinated gradient media used in the separation of viruses are derivatives of triiodobenzoic acid to which hydrophilic groups have been attached to increase water solubility. The ionic forms of these compounds include the sodium or *N*-methylglucamine salts of metrizoate, diatrizoate, and iothalamate, and the nonionic forms include metrizamide and Nycodenz. These materials form stable solutions at buoyant densities up to 1.45 g cm^{-3} . Iodinated compounds have several advantages, including much lower osmolarities and viscosities than sucrose at all densities. Gradients of these media can be pre-formed or generated in place.

Colloidal silica gradients have been used for several years, but only one preparation, namely Percoll (Pharmacia), has been developed for centrifugation. In this particular preparation the silica particles are coated with polyvinylpyrrolidone, which minimizes their interaction with biological material and also stabilizes the colloid against freezing and thawing and the presence of salts. Its solutions are isoosmotic and its low viscosity facilitates the rapid banding of viruses. However, Percoll is precipitated at low pH and solutions of high ionic strength destabilize the colloidal suspension. Gradients of Percoll readily self-form, or can be pre-formed using a simple mixer. Percoll forms suspensions at buoyant densities up to 1.13 g cm^{-3} . The removal of Percoll from virus solutions can be problematic because Percoll particles (17–30 nm in diameter) are very close in size of some viruses.

Proteins have a hydrated buoyant density of approximately 1.27 g cm^{-3} and can be used as gradient media, but no applications to viruses have been reported.

Types of Gradients

Pre-formed gradients for DGC of viruses can be continuous or discontinuous. Continuous gradients may be linear, convex, or concave and are usually prepared using a dedicated gradient former. Discontinuous or step gradients are prepared by successively layering solutions of different density. Pre-formed gradients must be handled very carefully prior to centrifugation to avoid gradient disruptions caused by vibration or temperature variations. The virus sample itself, which must have a density less than that of the top of the gradient, is gently layered onto the gradient before centrifugation is started. To minimize changes in the density profile at the top of the gradient, the sample volume should be small compared with the gradient volume.

For self-forming gradients the initial sample volume is not a concern, as the sample is either mixed with a concentrated solution of the gradient solute or solid gradient solute is added to give the correct initial density. The duration of centrifugation for self-forming gradients is longer than that for pre-formed gradients since time is required to form the gradient.

Rotors

DGC can be carried out in all the available types of rotors. Preparative centrifuge rotors are classified into four main types, namely swing-out (swinging bucket), fixed angle, vertical, and zonal. In swing-out or horizontal rotors, the tubes of sample solutions are placed in individual buckets that move out perpendicular to the axis of rotation as the rotor rotates. This creates a long migration path to separate viruses along the density gradient and requires a long period to achieve significant separation. Horizontal rotors can be spun to attain maximum speeds corresponding to 100 000 g or more.

In fixed angle rotors the tubes are at a fixed angle (varying from 14° to 40°) to the axis of rotation, and when the rotor rotates the solution reorients in the tubes. This reorientation enhances the loading capacity of the isopycnic gradients. Rotors with shallow angles are more efficient at pelleting because the sedimentation pathlength is shorter. Fixed angle rotors are designed to operate up to very high centrifugal forces ($>600\,000 \text{ g}$).

As the name suggests, in vertical rotors the tubes are held in a vertical position, and centrifugal forces similar to those for fixed angle rotors can be achieved. When the vertical rotor turns, the solution begins to reorient through 90° . Vertical rotors thus have short sedimentation pathlengths, so the diameter of the

tube and the capacities of the gradients in these rotors are higher than in horizontal and fixed angle rotors.

Zonal rotors are often used for gradient separation. Although the sample is pumped into a hollow rotor chamber, the working principle of these rotors is similar to that for vertical rotors, as it is the gradient solution that reorients during the run, before the sample is introduced under centrifugation. There are two types of zonal rotors, namely batch and continuous flow, that differ based on the volume of sample they can be used to process. Batch type centrifugation is typically used for 10–200 mL samples while for larger sample volumes of 100 L or more, continuous flow centrifugation is required. For volumes 200 mL to 100 L, vertical rotors can be used.

Recovery

Recovery of viral particles from DGC is performed either manually or automatically. After centrifugation density gradients can be recovered or unloaded from the bottom, middle or the top of the tube. The methods for unloading gradients from the bottom of the tube include bottom puncture of the tube or withdrawal using a narrow tube inserted through the gradient to the bottom. Targeted bands from within the gradient can also be unloaded by puncturing the tube at the appropriate position. The methods for unloading gradients from the top of the tube include direct unloading from the top or collection by upward displacement of the gradient by introducing a dense, preferably immiscible liquid at the bottom of the centrifuge tube. Automated collection systems with flow-arrest or volumetric monitoring are available commercially. Automated recovery systems require a heavy displacement solution such as 65% sucrose or Maxidens (Nyegaard & Co.), an inert, nonviscous organic liquid immiscible with aqueous gradients. Great care must be taken in fractionating gradients after centrifugation since resolution is easily lost at this stage. All operations should be designed to minimize disturbance of the gradient.

Conclusion and Future Developments

DGC is still the method of choice for the initial, relatively quick isolation of novel viral particles. The gradient medium, gradient shape, type of rotor, and mode of recovery are determined empirically,

for a particular viral preparation, to yield the highest possible recovery of bioactive purified virus and permit subsequent characterization and use.

The advent of gene therapy using viruses for gene delivery or as vaccine carriers has encouraged the development of scaleable procedures for virus isolation and purification based on centrifugation. With this impetus gradient media, rotor designs, and modes of recovery continue to be improved.

VITAMINS

Fat-Soluble: Thin-Layer (Planar) Chromatography

W. E. Lambert and A. P. De Leenheer,
Universiteit Gent, Gent, Belgium

Copyright © 2000 Academic Press

Introduction

Thin-layer chromatography (TLC) is a very widely used chromatographic technique allowing the separation of simple mixtures followed by a qualitative identification or a semiquantitative visual analysis of the samples. All this can be performed in an inexpensive and simple way without requiring highly sophisticated instrumentation.

On the other hand, high performance thin-layer chromatography (HPTLC) is a highly instrumental technique allowing fast and very efficient separations with quantitative results of accuracy and precision rivalling those obtained by the far more popular techniques such as high performance liquid chromatography (HPLC) and gas chromatography (GC). The small particle size (5 μm) and the more uniform layer of the stationary phase of the commercially pre-coated HPTLC plates are responsible for this increased efficiency and sensitivity.

This article focuses on the specific separation of fat-soluble vitamins by TLC. Strategies from sample preparation, stationary phases, mobile phases and detection modes will be discussed for each vitamin separately. However, from the recent reviews published biennially in *Analytical Chemistry* it can be seen that the number of new applications of TLC to the analysis of fat-soluble vitamins is diminishing all the time.

The chemistry (stability) of the different compounds, will be treated because of its importance in TLC analyses.

Vitamin A

The structures of vitamin A and of some related compounds are presented in Figure 1. The parent compound, all-*trans*-retinol or vitamin A, is an isoprenoid structure with five conjugated double bonds resulting in an absorption maximum at 325 nm (in *n*-hexane or ethanol), in a high molar extinction coefficient and in a sensitivity of the compound towards isomer formation and/or oxidation. The formation of isomers is catalysed by light and iodine while the relative amount of the isomers depends on the wavelength and on the solvent used. The four exocyclic double bonds can theoretically result in the formation of 16 isomers. All have been characterized. An increase in the number of *cis* bonds generally results in a lower absorption maximum as well as a decrease of the molar extinction coefficient relative to the all-*trans* isomer. Vitamin A and the Vitamin A-related compounds are also sensitive towards oxidation and peroxidation by contact with air. The presence of transition group metals is known to catalyse this reaction.

To prevent degradation it is imperative to take special precautions when working with vitamin A-related compounds, for example, storing the samples at very low temperature, working under subdued light, avoiding drastic reagents and contact with air or peroxide-containing organic solvents.

The lability of these compounds makes research in the vitamin A field a real analytical challenge. Especially during the TLC process, special precautions are necessary, as will be described below.

Chromatographic Conditions

TLC on polar inorganic nonmodified sorbents such as alumina and silica remains very popular. Silica plates can be activated by heating at 120°C for 1 h in an attempt to enhance resolution, while spraying the plates with a solution of an antioxidant has been reported to prevent degradation of the compounds on the plates.

As with what is known from liquid chromatography, chromatographic systems based on silica plates with eluents of hexane, petroleum ether or cyclohexane, with a variable amount of a more polar solvent such as 8% diethyl ether, 50% diethyl ether or 20% ethyl acetate, offer the best separation of the geometric isomers of vitamin A compounds. In a similar way, high performance silica gel thin-layer

plates eluted with diethyl ether-cyclohexane-acetone-glacial acetic acid allows the separation of all-*trans*- and 13-*cis*-retinoic acid in gel formulations (Table 1). Separation of vitamin A from the lipophilic vitamins is also possible on silica plates eluted with mixtures of benzene-petroleum ether-acetic acid. Under these conditions the water-soluble vitamins remain at the origin. Very often, classical TLC on silica plates serves as a kind of clean-up step before offline quantification, e.g. for the quantification of vitamin A in fruits and vegetables. With the introduction of the smaller HPTLC plates, more efficient separations together with shorter development times are possible. This has allowed the quantitative determination of retinol and of α -tocopherol in plasma with tocopheryl acetate as an internal standard.

In isolated cases kieselguhr plates or talc, starch or cellulose thin layers have been impregnated with 10% paraffin oil in cyclohexane. This was applied to a study of the hydrophobicity of a number of vitamin A-related compounds and for a separation of vitamin A-acetate from vitamin A-palmitate. For these studies the impregnated plates were eluted with mixtures of methanol-water (95:5, by vol.) and of acetone-concentrated acetic acid (30:20, by vol.).

Both the elution order of the compounds under investigation and the composition of the elution solvents clearly demonstrate a reversed-phase type of retention under these conditions.

Reversed-phase stationary phases such as RP-2 or C₁₈ are also used in the analysis of vitamin A-related compounds. The separation on the RP-2 phase, how-

ever, is less efficient than that obtained on paraffin oil-impregnated kieselguhr. Separation on a C₁₈ phase and on a silica phase (on one single plate) has been used in a two-phase two-dimensional TLC determination of all-*trans*- and 13-*cis*-retinoic acid in cream samples. The reversed-phase step served to separate the retinoic acid isomers from the cream excipients, while the silica sorbent was ideally suited for the separation of the two isomers from each other. Generally, on reversed-phase TLC plates, methanol or acetonitrile can separate retinol from retinyl acetate while dichloroethane with acetonitrile can separate the long chain retinyl esters.

Detection

Quenching the fluorescence of the indicator fixed on the thin-layer plate itself (F_{254}) is a very common and nondestructive way to localize spots on a TLC plate. Of course, this can also be applied to vitamin A compounds. Retinol and retinyl esters on the other hand can be identified by the yellow-green fluorescence they exhibit under 366 nm UV light. Other techniques to visualize vitamin A compounds include absorption of iodine vapours (with the formation of brown spots) or destructive procedures such as spraying with sulfuric acid.

Other spray reagents include SbCl₃ or SbCl₅ solutions in chloroform, a 5% solution of phosphomolybdic acid in ethanol and a mixture of equal volumes of a 1% aqueous solution of potassium permanganate and a 5% aqueous solution of sodium carbonate. After heating the plate coloured spots appear for vitamin A. The same reagents are often applied to visualize vitamins D and E.

As an alternative a large array of dyes has been evaluated as visualizing agents for fat-soluble vitamins, including vitamin A. The different dyes (aniline blue, alkaline blue, brilliant green, neutral red, bromocresol green, bromothymol blue, thymol blue, phenol red, helasol green, brilliant cresyl blue and bromophenol blue) are used as a solution of 50 mg of the dye either in 100 mL of water or in 100 mL of a 2% aqueous sodium hydroxide solution. Evaluation of the plates is then performed 20 min after spraying or after acceleration of the reaction by heating the plates at 110°C for 15 min.

For quantitative measurements, densitometric evaluation can be applied to vitamin A compounds. In this way, absorbance can be measured by diffuse reflectance at 290 nm using a mercury lamp, while UV spectra can be recorded between 200 and 400 nm with a deuterium lamp. Detection limits for retinol using this technique are around 160 ng mL⁻¹ using 200 μ L plasma. By using tocopheryl acetate as an

Figure 2 Structure of (A) vitamin D₂ (ergocalciferol) and (B) vitamin D₃ (cholecalciferol).

internal standard, the coefficient of variance (inter plate and intra plate) can be kept below 12.5%.

Using the dyes as a visualizing agent, the highest sensitivity on a silica plate can be obtained with bromophenol blue (in 2% aqueous sodium hydroxide) without heating the plate. Under these conditions 3 µg can be visualized. The same reagent applied on a partition-type TLC plate (silica gel impregnated with a 5% solution of paraffin oil in chloroform) resulted in a fivefold decrease in sensitivity towards vitamin A.

Vitamin D

Vitamin D and its structural analogues are a group of 9,10-seco-steroids: their basic structures are shown in **Figure 2**. The D₂ series (ergocalciferol) is of vegetable origin and has a side chain derived from ergosterol containing an additional C₂₂₋₂₃ double bond and a C₂₄ methyl group, whereas vitamin D₃ (cholecalciferol) is formed in the skin of humans and animals and has a side chain derived from cholesterol. The conjugated system of three bonds results in a molar extinction coefficient of 18 300 L mol⁻¹ cm⁻¹ with a λ_{max} at 264 nm. Both analogues are derived photochemically from their respective precursor (provitamin D). Indeed, irradiation of this provitamin D results in various photolysis products such as tachysterol, lumisterol and pre-vitamin D. Pre-vitamin D then undergoes spontaneous rearrangement to vitamin D. In the human body vitamin D₃ is extensively metabolized. The liver converts it to 25-hydroxy vitamin D₃ while further hydroxylation in the kidney yields, among others, 1,25-dihydroxy vitamin D₃. As with vitamin A, protection from light and from air is of great importance for the analysis of vitamin D by TLC.

TLC and, recently, HPTLC have found several applications in vitamin D analysis, including differen-

tiation of vitamin D analogues, separation of vitamin D from other lipids (e.g. sterols, other fat-soluble vitamins), determination of the purity of radiolabelled vitamin D derivatives and analysis of vitamin D metabolites as a part of radioligand assays.

Chromatographic Conditions

Polar inorganic sorbents such as silica gel or, occasionally, alumina have been applied to the separation of vitamin D analogues. In this way, provitamin D₃, tachysterol₃, lumisterol₃ and pre-vitamin D₃ were separated on silica gel and the eluting order of the compounds could be correlated with the increasing planarity of the compounds. Vitamins D₂ and D₃ can be separated on their basis of their hydrophobicity; the double bond in the hydrocarbon chain of vitamin D₂ results in lower hydrophobicity compared with vitamin D₃. This was proven by comparing the R_F values of the two compounds both in an adsorption system (silica gel eluted with benzene-methanol, 9:1) and in a partition system. For the latter experiment, kieselguhr plates impregnated with a 10% solution of paraffin oil in benzene were eluted with different mixtures of methanol-water or acetonitrile-water. In spite of the extra methyl function in the side chain of D₂ the double bond makes this compound more polar than D₃, as demonstrated by their R_F values in the latter system (**Table 2**).

For the separation of vitamin D from other lipids, e.g. in foods, in most cases silica gel plates are applied. In cases where vitamin D has to be separated from sterols (cholesterol, β -sitosterol, stigmasterol or lanosterol), however, alumina may be the preferred stationary phase because silica gel can show too high an adsorption strength towards free sterols.

In particular cases, multiple development of the plates may be necessary, e.g. when vitamin D has to be determined in cod liver oil. Despite the availability of column chromatographic procedures or, more

recently, of HPLC, TLC is still used in the clean-up of extracts of lipid-rich matrices such as foods, tissues, oils or multivitamin preparations. The same even holds true for applications of TLC in the sample preparation step for separation of the different metabolites of vitamin D. Of course, in biological matrices the content of the vitamin D metabolites is too low to allow visualization by spray reagents. Typically, the areas corresponding to the compounds of interest are then scraped off and wetted with a small volume of solvent to make it directly amenable to a quantitative radioligand determination.

Silica gel and silica gel impregnated with silver nitrate have also been used to monitor the purity of radiolabelled vitamin D. The advantage of the application of TLC for this type of study is based on the fact that TLC offers a total picture of all impurities, whereas in liquid chromatography it can never be totally excluded that some impurities are not eluted.

Polar organic sorbents (e.g. cellulose) or nonpolar bonded phases are infrequently used in vitamin D analysis by TLC. However, separation on kieselguhr plates impregnated with paraffin oil, described above, clearly demonstrates that nonpolar bonded phases are worth evaluation for the separation of D_2 from D_3 .

Detection

Although not very sensitive, UV absorbance or fluorescence quenching (the latter on plates containing a fluorescence indicator) are universal procedures that are valid for the detection of vitamin D.

green, can also be used to visualize vitamin D-related compounds.

As already mentioned, for quantification purposes of vitamin D-related compounds, TLC is often incorporated as a clean-up step before offline measurement either by gas chromatography-mass spectrometry (GC-MS) or radioimmunoassay (RIA). This clean-up function offers a certain future for TLC and HPTLC, especially for laboratories specializing in RIA and lacking HPLC equipment.

Vitamin E

Vitamin E is a collective term for tocopherols and tocotrienols, a series of potent antioxidants derived from 6-chromanol by substitution with a saturated (tocopherols) or partially unsaturated (tocotrienols) isoprenoid side chain and one to three methyl functions (Figure 3). The principal form is α -tocopherol (5,7,8-trimethyltolcol) which in nature occurs in the 2*R*, 4'*R*, 8'*R* configuration. Tocol can be regarded as the unsubstituted parent molecule, while α -, β - and γ - and δ -tocopherol form a homologue series of tri-, di- and monosubstituted tocols, respectively. The dimethyltolcols (β - and γ -tocopherol) are positional isomers.

All vitamin E derivatives have strong reducing properties, with α -tocopherol being the most biologically active homologue. By scavenging free radicals and other oxidative species, α -tocopherol is known to protect membrane lipids from peroxidation. Other functions described for vitamin E remain more controversial. In the absence of air, vitamin E derivatives are quite stable to heat and alkali. However, in the presence of air they are rapidly oxidized by alkali and metal ions. Vitamin E derivatives absorb light in the UV region (λ_{max} 292–295 nm; ϵ 3530 L mol⁻¹ cm⁻¹) and they are natively fluorescent (λ_{ex} 205 and 295 nm; λ_{em} 330 nm).

^aAll separations were done on silica plates.

Chromatographic Conditions

For TLC separation of vitamin E derivatives, silica gel plates have been widely used. Within the group of tocopherols migration is correlated with the degree of ring methylation. However, for the separation of β - from γ -tocopherol (two dimethyl tocols), often two-dimensional TLC is necessary with an eluent based on petroleum ether and diisopropyl ether for the second TLC run (Table 3).

Resolution of the naturally occurring tocopherols and tocotrienols also requires two-dimensional TLC. The separation between β -tocotrienol and γ -tocopherol, in particular, remains an analytical challenge. Both capillary GC and HPLC have now replaced TLC approaches, but the solvents used in HPLC often rely on solvent systems applied in earlier TLC separations.

Traditionally, TLC on silica gel or on alumina has also played an important role in the clean-up of extracts of biological materials for the spectrophotometric analysis of tocopherols/tocotrienols in the presence of a large excess of interfering lipids. The whole procedure, however, often included saponification, extraction, column chromatography and two successive TLC runs before the final spectrophotometric measurement.

Both silica gel and alumina lend themselves to separation of tocopherols from their decomposition products (α -tocopherylquinone, α -tocopherylhydroquinone) from other fat-soluble vitamins or from other lipophilic antioxidants such as butylated hydroxytoluene, butylated hydroxyanisole, ethoxyquin, gallate esters and ascorbyl palmitate.

More recently, reversed-phase chromatographic conditions have been evaluated for the separation of α -, β -, γ - and δ -tocopherol. Kieselguhr G plates impregnated with a 10% solution of paraffin oil in benzene and eluted with methanol-water (9:1, by

volume) offer the best separation. Of the four tocopherols considered, the difference between the R_F values of β - and γ -tocopherol was small.

Alternatively, reversed-phase C₁₈ plates have also been applied to the separation of α -tocopherol from other antioxidants or from the other tocopherols. A new and interesting trend consists of the separation of D and L enantiomers of tocopherol on chiral plates (stationary phase, chiral plate solvent: propanol-water-methanol (8.5:1.0:0.5, by volume) activated by heating at 100°C for 15 min). Because of the different biological activities of both enantiomers, this type of separation should be further investigated.

Detection

The commonest mode of detecting tocopherols and tocotrienols on TLC plates is based on quenching the fluorescence of supports impregnated with a fluorescent indicator. Alternatively, tocopherols and tocotrienols can be visualized by nonspecific procedures such as charring preceded by spraying with sulfuric acid, perchloric acid, nitric acid or 10% copper(II) sulfate in 8% phosphoric acid. More specific visualization procedures are based on the reducing properties of the vitamin E-related compounds. In this way, ferric ions are reduced to ferrous ions which react with α , α' -dipyridine or bathophenanthroline to form a red-coloured complex (Emmerie-Engel reaction). Phosphomolybdic acid and a 20% antimony pentachloride solution in chloroform both produce characteristic colour reactions allowing β -tocopherol to be distinguished from γ -tocopherol, or all four tocopherols from each other. Quantification of vitamin E-related compounds after TLC separation can be performed either off-plate or on-plate. Off-plate methods include scraping the areas of interest from the plate and eluting the compounds with an organic solvent, followed either by a colorimetric measurement or

Figure 4 Structure of vitamin K and related compounds.

by GC determination. On-plate quantification is based on densitometry of the coloured spots obtained with chromogenic spray reagents, on the native UV absorbance or on the native fluorescence properties of the compounds of interest.

Vitamin K

All K-vitamins are derivatives of the same 2-methyl-1,4-naphthoquinone nucleus. The number of isoprene units or the number of carbon atoms in the side chain can be used to characterize the molecules. Accordingly, MK_4 contains four isoprene units, or $K_{1(20)}$ has 20 carbon atoms in the side chain (Figure 4). Three molecules, each representative of a particular group of K-vitamins, are of special importance:

1. Phylloquinone (Vitamin $K_{1(20)}$) is synthesized by green plants and is found in chloroplasts of photosynthetic plants. Epoxidation of the double bond between carbons 2 and 3 of the naphthoquinone nucleus results in $K_{1(20)}$ -epoxide
2. Menaquinone- n , also called MK_n , is characterized by a propenyl side chain often containing a large number of isoprene units (up to 13), with n indicating the number of units. Menaquinones (ranging from MK_4 to MK_{13}) are synthesized by bacteria (e.g. *Escherichia coli* and *Staphylococcus aureus*)
3. Synthetic vitamin K_3 (menadione or MK_0) does not occur in nature. In the body, menadione exhibits vitamin K activity by virtue of its *in vivo*

conversion to menaquinones, chiefly MK_4 , by microorganisms or by alkylating enzymes.

Phylloquinone and the other K-vitamins are destroyed in alkaline media and are sensitive to daylight (isomer formation). The K-vitamins are easily reduced but are fairly stable towards oxidizing conditions and heat. Both vitamin $K_{1(20)}$ and MK_n show a characteristic UV absorption spectrum with maxima at 244, 249, 263, 270 and 331 nm (in methanol). Their molar extinction coefficient at 249 nm is of the order of $20\,000\text{ L mol}^{-1}\text{ cm}^{-1}$.

Chromatographic Conditions

TLC procedures for vitamin K can be divided into three main types:

1. adsorption chromatography on silica plates for the separation of *cis-trans* isomers
2. argentation chromatography (also on silica layers) to separate saturated and unsaturated homologues of vitamin K
3. reversed-phase chromatography for the separation of methylated and demethylated K-vitamins

These three systems are complementary and will be treated below.

One major advantage of TLC on silica gel is that silica gel has little or no tendency to catalyse the degradation of vitamin K. This is in contrast to alumina-based separations. Separations on silica are mainly based on differences in polarity, which makes the procedure the method of choice for the isolation

of vitamin K from other lipids. In this way, TLC on silica plates developed with light petroleum ether–diethyl ether (85:15, by volume) is included in the sample preparation for the determination of vitamin K in lipid-rich animal tissues. Although no recent publications have been found, TLC on silica plates is especially suited for the separation of geometric isomers (*cis-trans* isomers).

Silica plates have been impregnated with 5–20% silver nitrate. Under these conditions lipids containing unconjugated double bonds in their side chain form complexes with the silver ions and show a higher retention than the saturated counterparts. Consequently, separation between saturated ($K_{1(20)}$), partly saturated [MK-*n* (H_n)] and fully unsaturated homologues (MK-*n*) becomes possible. On the other hand, in argentation chromatography the resolution between *cis* and *trans* isomers is completely lost. Silver ions are not destructive for vitamin K, so samples can be eluted from the silica afterwards. However, for high molecular weight menaquinones, irreversible adsorption to argentation TLC plates has been reported.

Unlike in argentation TLC, where retention is correlated to the degree of unsaturation, in reversed-phase TLC the retention is based on the length of the side chain. Both techniques are thus perfectly complementary for the separation of menaquinones.

In addition to silica plates and argentation TLC, reversed-phase TLC has been applied to vitamin K-related compounds. Typical eluents consist of water and an organic solvent such as methanol, acetonitrile or tetrahydrofuran. However, because of wettability problems with aqueous solvents, often nonaqueous reversed-phase conditions are used with dichloromethane and methanol (70:30, by vol.) as eluting solvent.

Detection

As with the other fat-soluble vitamins, fluorescence quenching can be applied to localize the position of vitamin K-related compounds on a TLC plate. More sensitive but often destructive for the compounds of interest include spray reagents such as 70% perchloric acid (5–10 min at 105°C), a 0.05% solution

of rhodamine B in ethanol, a 0.2% anilinonaphthalene sulfonic acid solution in methanol and a 10% solution of phosphomolybdic acid in ethanol.

Again densitometry (based on reflectance, transmission) has completely replaced visual inspection as well as the offline quantification after elution of the bands. Densitometry allows internal standardization and results in a higher degree of sensitivity and speed of analysis.

General Conclusions

From the above overview it should be clear that TLC is no longer the method of choice for the analysis of fat-soluble vitamins. The major reason for this lies in the great progress made in HPLC. Newer trends such as HPTLC and densitometric scanning may give TLC a new momentum but never to the extent that it will again supersede HPLC as a routine technique for the determination of fat-soluble vitamins in foods or biological materials. Undoubtedly, however, modern instrumental TLC can offer automation, improved repeatability and more accurate quantification compared to classical TLC.

Introduction

Vitamins are a group of organic compounds essential to life in very low concentrations. They are either

insufficiently produced by the body or not at all. Inadequate vitamin intake causes deficiency disorders in both humans and animals. The various vitamins are not related to each other chemically and have quite different properties. Two main groups, the fat-soluble and the water-soluble vitamins, may be distinguished.

Increased interest in vitamin research, together with the requirements of food and pharmaceutical quality control, have led to a proliferation of methods for vitamin assay, especially by liquid chromatography (LC). Bioassay methods are no longer used, but microbiological methods, physicochemical methods and chromatographic procedures (thin-layer chromatography, gas chromatography and liquid chromatography) are commonly employed. Classical open-column liquid chromatography is occasionally used, but modern high performance liquid chromatography (HPLC) is by far the technique of choice for vitamin analysis and is the subject of this article.

Vitamin analysis is performed to establish the vitamin status of humans or animals, to determine the potency of foods and feeds, and to monitor the storage stability of vitamin-containing pharmaceutical preparations. Information on the physicochemical and biochemical aspects of vitamins and vitamin intake is widely available in the literature (see Further Reading).

Sample Preparation

Vitamin A, the carotenoids, and vitamins E, D and K belong to the group of fat-soluble vitamins, which are soluble in organic solvents. The water-soluble vitamins B₁, B₂, B₆, B₁₂, C, biotin, folic acid, pantothenic acid, niacin, choline and inositol are soluble in water (Table 1). The structures of some fat-soluble and water-soluble vitamins are shown in Figures 1 and 2.

Sample preparation prior to the final chromatographic analysis is highly dependent upon the nature of the matrix. Minimal preparation is necessary for the analysis of concentrated solutions. For complex biological matrices more elaborate sample preparation procedures may be necessary. A 'recovery test' is highly recommended. This consists of adding a known amount of pure vitamin, approximatively equal to the estimated value in the sample, and processing the fortified sample in the same way as the sample itself. Loss of vitamin during analysis should not exceed 6%.

Fat-Soluble Vitamins

For fat-soluble vitamin assays all manipulations must be carried out in subdued light, in dark glass vessels, and in a nitrogen atmosphere to avoid isomerization and oxidation.

In foodstuffs, major interferences in assays for vitamin A, carotenoids, and vitamins E, D and K are caused by the large excess of other lipids. The vitamin A, carotenoids, and vitamins E and D contents are measured generally after alkaline hydrolysis with ethanolic KOH under a nitrogen stream at 60–80°C for 20–30 min in the presence of an antioxidant. Pyrogallol, hydroquinone, ascorbic acid (vitamin C) and butylated hydroxytoluene (BHT) are the most common antioxidants used during this manipulation. After saponification the free retinol, carotenoids, vitamin E and vitamin D are extracted into *n*-hexane or petroleum ether and evaporated to dryness. Vitamin A, carotenoids and vitamin E are redissolved in an organic solvent compatible with the chromatographic method to be employed. Vitamin K needs milder conditions for extraction from protein. Both vitamins D and K may require further purification before chromatography.

In the analysis of serum, vitamin A or retinol is liberated from its binding protein by denaturation with acetonitrile, ethanol or methanol. An internal

standard, e.g. either retinyl acetate or tocol, is generally added for quantitation purposes. After protein precipitation the free retinol is extracted with 1% BHT in *n*-hexane solution, evaporated to dryness under nitrogen and subjected to chromatographic separation as above. Vitamin E and carotenoids are extracted in the same manner. Vitamins A, E and carotenoids can be simultaneously injected for LC separation. The analysis of vitamin D and trace quantities of vitamin D metabolites, e.g. 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol, and

also the analysis of vitamin K in human plasma, require an additional step for prepurification using column extraction or a semipreparative LC system prior to the final HPLC separation.

Water-Soluble Vitamins

Water-soluble vitamins are in general more stable than fat-soluble vitamins, although vitamin B₂ and to a lesser extent vitamin B₁₂ (folic acid) are light sensitive. All manipulations should therefore be performed in subdued light. No special treatment of samples in

pharmaceutical preparations is required before chromatography. In biological fluids or foodstuffs pre-purification and/or derivatization of the compounds are necessary before LC separation. The methods include acid extraction followed by enzymatic hydrolysis with takadiastase, papain or acid phosphatase, sometimes with pre-column or post-column chromatography. Trichloroacetic, perchloric and metaphosphoric acids are usually preferred for acid extraction. Depending on the aim of the investigation, vitamins can be determined in their free forms or in both free and phosphorylated forms. In the latter case the enzymatic hydrolysis step is omitted.

In blood, plasma and food, vitamin B₁ in protein-free extract is oxidized by agents such as [Fe(CN)₆]³⁻, cyanogen bromide or mercuric chloride to thiochrome in a pre- or post-column chromatography reactor. For pre-column chromatography two different procedures are used. In the first, the thiochrome extract is neutralized by concentrated phosphoric acid to ensure a pH level compatible with the C₁₈ column used for the separation and to eliminate possible pH-dependent alkaline degradation of thiochrome to its disulfide. It is then centrifuged and the supernatant injected into the HPLC. In the second procedure, isobutyl alcohol is used to extract thiochrome after alkaline oxidation. Aliquots of the extracts are then chromatographed.

After acid extraction vitamin B₂ is readily detected owing to its intense fluorescence.

Since vitamin B₆ is present in six chemical forms, there are methods for the simultaneous separation of the three free forms and the three phosphorylated forms as well as methods for determining the sum of all the forms. Pyridoxamine is transformed into pyridoxal by reaction with glyoxylic acid in the presence of Fe²⁺ as catalyst. The pyridoxal is then reduced to vitamin B₆ pyridoxol by the action of sodium borohydride in an alkaline medium before LC separation. Semicarbazide is also used for post-column derivatization of vitamin B₆.

In multivitamin-multimineral preparations, vitamin B₁₂ or cyanocobalamin is extracted with a mixture of dimethyl sulfoxide (DMSO) and water, or ammonium pyrrolidine dithiocarbamate and citric acid in DMSO and water. The extract is centrifuged and the supernatant is diluted with water before concentration and clean-up by solid-phase extraction using a quaternary amine and a phenyl column in series before LC separation. There are few LC methods for the determination of vitamin B₁₂ in human plasma and food.

In biological fluids and foodstuffs a treatment for removing protein is a major requirement for vitamin C assay. Protein precipitation may be done by organic

reagents (methanol or acetonitrile) or mineral acids (perchloric, metaphosphoric acid, etc.). Aqueous solutions of vitamin C are rapidly oxidized on exposure to air. Stabilizers such as hydrogen sulfide and 1,4-dithio-DL-threitol have also been employed. The deproteinization may be followed by an enzymatic oxidation of ascorbic acid to dehydroascorbic acid, which is transformed with 1,2-phenylenediamine to its quinoxaline derivative for final separation.

Biotin, or vitamin H, is very stable. However, the limitation of HPLC lies in the lack of a suitable detection system. There are applications of LC to pharmaceutical products containing at least 300 µg biotin per tablet. In pharmaceutical products and feed premix, biotin is extracted from the matrix with buffer, followed by purification and concentration by solid-phase extraction and separation by LC. However, there are few LC methods for the estimation of biotin in biological samples.

Folic acid (pteroylglutamic acid; also called vitamin M) and its derivatives are stable substances. Folic acid may be determined simultaneously with other water-soluble vitamins in pharmaceutical preparations. In food products folates are extracted from the matrix with buffer and enzymes (e.g. hog kidney and chicken pancreas, or rat plasma conjugase, α -amylase and protease together), followed by purification and concentration by solid-phase extraction or with affinity chromatography before final separation.

In pharmaceutical preparations panthenol, pantothenic and its salt (vitamin B₅) are extracted with a phosphate solution. The extract is centrifuged, filtered and separated by LC. There are few methods for the determination of pantothenic acid and its salt in food products and biological fluids.

Niacin (or nicotinic acid) and nicotinamide are the two different forms of vitamin PP (so called for its pellagra-preventive factor). Nicotinamide is the form of the vitamin generally found in human plasma. Plasma is deproteinated with acetone/chloroform, the organic layer evaporated to dryness, and the methanolic extract of the residue separated by a reversed-phase HPLC. Isonicotinic acid is used as an internal standard. Urine is purified by extraction with chloroform, the aqueous phase evaporated, and taken for separation by LC. In foods vitamin PP is present mostly in its phosphorylated forms. Hydrolysis is necessary to break the ester bonds, releasing the total vitamin PP content of the food for assay. In food products niacin is extracted with buffer and enzyme. The sample extracts are purified through an ion exchange column (e.g. Dowex 1-X8 resin) before HPLC.

In multivitamin preparations 0.1 mol L⁻¹ hydrochloric acid is used to extract the vitamins and

DMSO containing anhydrous citric acid is used to disperse the multivitamin-multimineral preparation, since vitamin B₆ is not completely extracted by either 0.1 mol L⁻¹ hydrochloric acid or DMSO owing to adsorption of the vitamin to the minerals. The extraction of nicotinamide is not impaired by the addition of citric acid to DMSO.

Choline in plant material is extracted with isopropanol containing internal standards and *p*-nitrobenzylhydroxylamine hydrochloride for the formation of *p*-nitrobenzyl oximes. The extract is purified by solid-phase extraction (C₁₈ and ion exchange), after which the choline fraction is benzoylated to yield UV-absorbing derivatives. In biological samples choline is extracted with formic acid in acetone containing an internal standard. After purification the sample is separated by LC.

For the analysis of inositol mono- and diphosphate isomers in foods the method involves extraction of samples with hydrochloric acid and separation of inositol phosphates by anion exchange chromatography.

Liquid Chromatography

Liquid chromatography is an extremely valuable method for separation, identification and quantitation of the different vitamins. Excellent separations can be achieved in a reasonable time for routine analysis.

Fat-Soluble Vitamins

For fat-soluble vitamins normal-phase and reversed-phase chromatography are used.

In the normal-phase modes, silica and nonpolar mobile phases containing *n*-hexane or petroleum ether with a small percentage of a more polar solvent are used. Addition of a small amount of water or alcohol (e.g. ethanol) regulates the sorbent activity, reduces peak tailing and gives better reproducibility of retention times. Silica is the adsorbent of choice for the separation of *cis/trans* isomers and diastereoisomers. Selectivity on silica is determined by the number and the nature of the functional groups as well as the overall steric configuration (position of the double bonds) of the molecule (Figure 3).

In the reversed-phase mode, hydrophobic column packings (C₁₈, C₈, etc., bonded to a silica surface) are used together with an aqueous buffered mobile phase and a water-miscible organic solvent (i.e. methanol, acetonitrile).

Retinol analysis in biological fluids and foods is performed using both normal-phase and reversed-phase chromatography. For normal-phase (or liquid-solid) chromatography there is compatibility

Figure 3 Example of an HPLC separation of α -, β -, γ - and δ -tocopherol from a wheat germ oil sample with α -tocopherolacetate added. Peaks: 1, α -tocopherolacetate; 2, α -tocopherol; 3, α -tocotrienol; 4, β -tocopherol; 5, γ -tocopherol; 6, δ -tocopherol.

Experimental conditions: stationary phase, Lichrosorb Si 60, 7 μ m; column dimension, 250 \times 4.6 mm; mobile phase, *n*-hexane/dioxane (97 : 3 v/v); flow rate, 1.0 mL min⁻¹; injection volume, 20 μ L; detection, fluorimetric with excitation at 295 nm and emission at 330 nm. (Reproduced with permission from Federal Office of Public Health, 1989.)

between the sample extraction solvent and the LC mobile phase; this avoids peak artefacts, especially for lipid extracts. Geometrical isomers such as 11-*cis*, 13-*cis*, 9-*cis* and all-*trans* retinol are well resolved. Retinol serum determination by reversed-phase chromatography allows the use of retinol acetate as internal standard which is well separated from retinol, unlike the case for liquid-solid chromatography. Meanwhile there is an additional step of evaporation of the extraction solvent in the sample preparation procedure before LC.

The most appropriate systems for the separation of polar and nonpolar carotenoids include the use of polymeric C₁₈ or C₃₀ bonded phases without end-capping in conjunction with a moderate pore-size packing column and a methanol-based mobile phase (to obtain a good recovery). *Cis*-isomers of β -carotene are largely resolved from each other and from other carotenes. Separation of lutein and zeaxanthine is also obtained with this system. Better separations of the xanthophylls are also observed. Accurate carotenoid measurements require the right selection of column and mobile phase and, due to the large degree of variability in the purity of commercial carotenoid

Figure 4 Chromatogram of a human serum sample. Peaks: RET, retinol; IS, retinol acetate (internal standard); LUT, lutein; ZEA, zeaxanthin; δ -TOC, δ -tocopherol; γ -TOC, γ -tocopherol; α -TOC, α -tocopherol; LYC, lycopene; α -CAR, α -carotene; β -CAR, β -carotene; *trans*-CAR, *trans*- β -carotene; a, unidentified carotenoid.

Experimental conditions: stationary phase, Lichrosorb RP-18, 7 μm ; column dimension, 250 \times 4.6 mm and 15 \times 3.2 mm guard column; mobile phase, acetonitrile/tetrahydrofuran/methanol (68 : 22 : 7 v/v/v) adjusted to 100% with ammonium acetate; flow rate, 1.5 mL min⁻¹; injection volume, 15 μL ; detection, programmable and variable-wavelength UV/Vis, 325 nm from 0 to 3.0 min, 450 nm from 3.0 to 4.9 min, 290 nm from 4.9 to 7.4 min, 470 nm from 7.4 to 12.0 min and 450 nm from 12.0 to 15.0 min. (Reproduced with permission from Bui, 1994.)

preparations, special precautions must be taken during calibration. Simultaneous determination of carotenoids, retinoids and tocopherols in serum and foods is performed on a C₁₈ column using wavelength-programmable UV-visible (**Figure 4**), fluorescence or electrochemical detection.

The same separation conditions are used for the separation of α -tocopherol and retinol in biological fluids and foods. α -, β -, γ - and δ -Tocopherol as well as α -, β -, γ - and δ -tocotrienol are well resolved only by normal-phase chromatography. On an RP-18 column α -, β - and δ -tocopherol isomers are all separated, but not β - and γ -tocopherols. Tocol as internal standard is also used for vitamin E determination in serum.

Retinol and α -tocopherol in biological fluids, foods and pharmaceutical preparations can be separated simultaneously by normal- or reversed-phase HPLC.

In biological fluids analyses of vitamin D and its metabolites are performed using solid-phase extraction (SPE) cartridge coupled to semipreparative HPLC on a silica column and analytical HPLC on an octadecyl (C_{18}) column with UV or electrochemical detection (**Figure 5**). They can also be purified by one or two preparative HPLC steps on silica and quantified

Figure 5 Chromatogram of HPLC-ECD for 24,25-dihydroxycholecalciferol (24,25-(OH)₂D₃).

Experimental conditions: stationary phase, Nucleosil C₁₈, 5 µm; column dimension, 300 × 7.5 mm; mobile phase, 5% (v/v) methanol in acetonitrile with 0.025 mol L⁻¹ HClO₄; flow rate, 1.2 mL min⁻¹; injection volume, 50 µL; detection, dual-electrode electrochemical detection: detector 1 (+0.20 V); detector 2 (+0.60 V). (Reproduced with permission from Masuda *et al.*, 1997.)

by HPLC on a C₁₈ column with UV detection. Vitamin D₂ or D₃ may be used as internal standard (Figure 6).

The analysis of vitamin K (phyloquinone, menaquinone and epoxides), like vitamin D, uses normal-phase semipreparative LC followed by an analytical reversed-phase column with UV or electrochemical detection (**Figure 7**). Water-soluble menadione sodium bisulfite or vitamin K₃ in animal feeds is determined by reversed-phase HPLC with UV detection. To improve vitamin K₃ detection limits, post-column reaction fluorimetric detection is used. Menadione is hydrogenated by sodium borohydride to 2-methyl-1,4-dihydroxynaphthalene, which is detected fluorimetrically.

Water-Soluble Vitamins

Water-soluble vitamins are separated using ion exchange (IEC), normal-phase or reversed-phase chromatography.

Ion exchange chromatography is the preferred method of separation for the analysis of strongly ionic compounds. The chromatographic separation may be optimized by altering the pH or ionic strength of the mobile phase. Reversed-phase chromatography is the method of choice for water-soluble vitamins. Reversed-phase columns such as C₁₈ and mobile phase NH₂ have been employed. The mobile phase is a mixture of methanol or acetonitrile with an acetate or phosphate buffer. For ionic compounds the reversed-phase ion pair mode is generally used. Unlike conventional

Figure 6 Analytical HPLC chromatograms of (A) standard mixture of ergocalciferol (D₂) and cholecalciferol (D₃); (B) D₂ (internal standard, IS) and D₃ in chicken sample; and (C) D₂ (IS) and D₃ in pork liver.

Experimental conditions: stationary phase, Zorbax ODS + Vydac 201 TP 54 5 μm ; column dimension, 250 \times 4.6 mm; mobile phase, 4% water in methanol; flow rate, 1.0 mL min⁻¹; injection volume, 50 μL ; detection, UV at 264 nm. (Reprinted from Horvath CsG (ed.) (1980) *High Performance Liquid Chromatography*, New York: Academic Press. Copyright © 1980 by Academic Press.)

IEC, this technique can separate nonionic and ionic compounds simultaneously. The chromatographic separation may be optimized by altering the ion pair reagent, pH and ionic strength of the mobile phase.

Water-soluble vitamins (vitamin B₁, thiamin, B₂, riboflavin or riboflavin 5-monophosphate; B₆, pyridoxine and nicotinamide) in commercial vitamin preparations can be separated using either strong cation exchange resins or reversed-phase chromatography using an ion pair reagent (e.g. sodium alkane-sulfonate, dioctyl sodium sulfosuccinate, tetrabutyl ammonium phosphate) in the eluent with UV detection.

Similar LC methods are used for the separation of thiamin in foods and biological fluids, usually with fluorescence detection. In pre-column procedures, silica, C₁₈, NH₂ and poly(styrene-divinyl benzene) phases are used. Since the intensity of thiochrome fluorescence depends on pH and reaches a steady

level at pH > 8, the mobile phase should contain a buffer. Polymeric C₁₈ packings are more suitable for these high pH conditions (Figure 8).

C₁₈ columns are used for the determination of riboflavin and its derivatives, flavin mononucleotide (FMN) and flavin-adenine dinucleotide (FAD). The compounds are separated isocratically with a mixture

with or without ion pair reagents; detection is by fluorimetry (Figure 10). The vitamin B₆ content of foods can also be determined by ion pair HPLC after

pre-column derivatization of the free and phosphorylated vitamin into pyridoxol (Figure 11).

Vitamin B₁₂ is separated from other water-soluble vitamins in pharmaceutical preparations by reversed-phase using a methanol/water gradient with detection at 550 nm (Figure 12).

Reversed-phase chromatography is mostly used for ascorbic acid determination. In foods total vitamin C (ascorbic acid and its oxidized form, dehydroascorbic acid) are determined using ion pair chromatography with UV detection. In biological fluids and foods total vitamin C, as its quinoxaline derivative, is separated on a C₁₈ column with fluorescence detection. The determination of ascorbic acid in plasma can also be achieved using a C₁₈ column and electrochemical detection. Another procedure for vitamin C determination consists of first measuring the ascorbic acid present, then reducing the dehydroascorbic acid, at neutral pH, with dithiothreitol, and finally measuring the total ascorbic acid. The dehydroascorbic acid is determined by difference. The separation is on a C₁₈ column with electrochemical detection.

After a clean-up procedure, biotin in pharmaceutical products is assayed using a C₁₈ column with methanol/water as the mobile phase and UV detection. Extracts of folates (folate monoglutamates and folic acid) in food and biological samples after purification are separated by gradient elution and UV or fluorescence detection (Figure 13).

Pantothenic acid is separated from other water-soluble vitamins with an isocratic system on an aminopropyl bonded phase using a mixture of acetonitrile/phosphate buffer as mobile phase and UV detection (Figure 14). Panthenol in multivitamin

Experimental conditions: stationary phase, Hibar II Lichrosorb NH₂ 10 μ m; column dimension, 250 \times 4.6 mm; mobile phase, 0.005 mol L⁻¹ monobasic potassium phosphate (pH 4.5)/acetonitrile (13 : 87 v/v) 0.01 mol L⁻¹ 1-octanesulfonic acid; flow rate, 2.0 mL min⁻¹; injection volume, 10 μ L; detection, UV at 210 nm. (Reproduced with permission from Hudson and Allen, 1984.)

preparations is determined on a C₁₈ column with a gradient system using an ion pair reagent (e.g. sodium hexanesulfonate) and UV detection. Niacin and nicotinamide are also separated on a C₁₈ column using an ion pair reagent with UV detection. Isonicotinic acid is used as an internal standard.

Cation exchange chromatography has been used to determine with UV or electrochemical detection. Separations of inositol mono- and diphosphate isomers in foods is performed on an anion exchange column using a sodium acetate in sodium hydroxide gradient with electrochemical detection.

Future Developments

Liquid chromatography is the method of choice for vitamin analysis in pharmaceutical products, foods, feeds and especially in biological fluids. In biological sample analysis LC affords separation of the vitamins, their related compounds and various metabolites for nutrition research. The main problem encountered in biological materials is the detection limit, particularly for water-soluble vitamins. There are two main areas where developments are necessary for future vitamin LC. First, automatic sample preparation techniques involving vitamin purification and enrichment, e.g. automating solid-phase extraction, need to be improved. Second, the coupling LC and mass spectrometric (MS) detection needs to be further developed. These techniques may become leading methods in vitamin analysis in the future.

Water-Soluble: Thin-Layer (Planar) Chromatography

J. C. Linnell, Royal Free and University College Medical School, London, UK

Copyright © 2000 Academic Press

As a tool, chromatography has long been important for the separation of vitamins from complex mixtures and their initial isolation and identification would have been greatly hampered without the use of paper, column or thin-layer chromatography (TLC). While more sophisticated chromatographic techniques are now widely available, TLC has great advantages in terms of its simplicity and flexibility of use.

The vitamins classified as water-soluble are all compounds important in human metabolism either as coenzymes or their precursors which the body cannot make for itself (Figure 1). The recommended daily allowance (RDA) of each vitamin ranges from hundreds of milligrams to just a few micrograms a day (Table 1). These compounds have few properties in common apart from their water-solubility, but this fact alone makes TLC an excellent technique for their separation, particularly in pharmaceutical preparations and food products. Even at physiological concentrations, TLC is widely used after extraction of the vitamins from tissues or body fluids. This generally needs to be under acid conditions. Since most of these compounds are unstable at high pH. Some are in addition very light-sensitive. Following TLC separation, special methods of detection may also be required, since tissue levels of most water-soluble vitamins are low or very low.

Thiamin (Vitamin B₁)

Thiamin occurs in plant and animal tissues and the richest sources are seeds and nuts, peas and beans, cereals and yeast. Fish and meat, notably pork, are also good sources. Thiamin is commonly available as its monohydrochloride, but it also forms acid salts and esters with nitric and phosphoric acids. Metabolically, thiamin is required as the coenzyme thiamin pyrophosphate for the mitochondrial metabolism of glucose and pyruvate.

Thiamin may be extracted from tissues, foodstuffs or pharmaceutical preparations with aqueous alcohol mixtures at a pH of 4–6 and separated from closely related compounds and metabolites by TLC on cellulose or silica gel. Various mobile phases have been successfully used, including isopropanol–water–trichloroacetic acid–ammonia (71 : 9 : 20 : 0.3) and butan-1-ol–acetic acid–water (40 : 10 : 50). Thiamin may be separated from its hydrolysis and oxidation products by TLC/densitometry and other chromatographic techniques have been reviewed. Sandwich-type chambers afford rapid separation of thiamin from other water-soluble vitamins by TLC on silica gel GF254 and the spots then located under UV light. An alternative technique for the quantitation of thiamin in pharmaceutical products involves the use of high performance TLC (HPTLC) and post-separation derivatization with a hexacyanoferrate (III)-sodium hydroxide reagent and fluorodensitometry, sensitive down to 500 pg per spot. Other modifications include the use of a fibreoptic probe

Figure 1 Structural formulae of water-soluble vitamins.

Table 1 Recommended daily allowances^a water-soluble vitamins

<i>Vitamin</i>	<i>RDA</i>
Ascorbic acid	30–75 mg
Nicotinic acid	15–20 mg
Pyridoxine	1–3 mg
Riboflavin	1.5–2.0 mg
Thiamin	1–2 mg
Folic acid	300 µg
Cobalamin	1–2 µg

^aThere is no quoted RDA for biotin or pantothenic acid.

to improve measurement of thiamin in the nanogram range.

Riboflavin (Vitamin B₂)

Riboflavin and other flavinoids occur in dairy produce, meat and to a lesser extent in cereals. Flavins are stable to heat and acid but are destroyed by exposure to light. Ultraviolet irradiation of riboflavin in acid or neutral solution gives rise to the fluorescent compound lumichrome, whereas in alkaline solutions irradiation produces lumiflavin. Flavins are required in the body as their coenzymes flavin mononucleotide and flavin adenine dinucleotide, which are involved in redox reactions involving one- and two-electron transfers and linked to many energy-dependent processes in the body.

Pharmaceutical preparations containing riboflavin may be analysed by applying concentrated ethanolic extracts to silica gel TLC plates developed in butanol–benzene–acetic acid–water (8 : 7 : 5 : 3) or butanol–acetic acid–water (9 : 4 : 5). Foods, tissue samples and urine each require particular methods of sample preparation and these methods and the solvent systems successfully employed have been reviewed elsewhere. A dark room is required for sample preparation and chromatography of flavins to prevent photolytic degradation. The fluorescent property of flavins provides a convenient means of detection and spots may be located under radiation at 254 and 366 nm. HPTLC followed by fibreoptic fluorimetry has been used to measure riboflavin in vitamin mixtures and can detect 48–320 ng. Separation is also effective on mixed-layer plates of GDX-102 and silica gel G (1 : 1) pre-coated with hexadecyltrimethylammonium bromide, developed in 60–70% ethanol.

Nicotinic Acid (Vitamin B₃)

Nicotinic acid (niacin) and various nicotinamides are sources of the coenzyme nicotinamide adenine dinucleotide, synthesized in the mitochondria and vital for

oxidative energy production in many metabolic reactions. Niacin is normally acquired from a balanced diet of meat, fish, whole cereals and yeast. Peas, beans, nuts, fruit and vegetables are also good sources of this vitamin.

Analysis of powdered preparations containing nicotinic acid has been achieved on silica gel plates impregnated with zinc acetate, developed in butanol–benzene–acetic acid–water (8 : 7 : 5 : 3) or butanol–acetic acid–water (9 : 4 : 5) to provide a self-indicating system. An overpressure chromatographic procedure using HPTLC silica gel plates and a mobile phase of butan-1-ol–pyridine–water (50 : 35 : 15) is also effective. This method uses photodensitometric detection to separate nicotinamide from other vitamins and the method is fast, accurate and specific. Other methods based on HPTLC and fibreoptic fluorometric quantitation have been described in which nicotinic acid is converted to a fluorescent derivative before chromatography. After separation, the plate is scanned by a bifurcated fibre-optic which transmits the excitation radiation and collects the signal emitted from the plate. Good calibration curves have been obtained in the range 10–100 ng nicotinic acid.

Pantothenic Acid (Vitamin B₅)

Pantothenic acid is required in the formation of acetyl coenzyme A which holds a key position in many metabolic pathways. Only the natural dextrorotatory form is active. Pantothenic acid is found in most foods of plant and animal origin and good sources include liver, kidney, wheat germ, royal jelly, peanuts, spinach, cheese and peas. There is no quoted RDA, though most diets provide at least 10 mg per day.

Panthenol and pantothenic acid have been identified and quantified in pharmaceutical preparations by extraction with ethanol or benzyl alcohol and separated by TLC on silica gel plates developed in propan-2-ol–water (85 : 15). Spots are measured by spectrodensitometry. Postaire has applied the over-pressure derivatization technique following separation of calcium pantothenate from other hydrophilic vitamins on silica gel HPTLC layers developed in butan-1-ol–pyridine–water (50 : 35 : 15).

Pyridoxine (Vitamin B₆)

Pyridoxine is found chiefly in animal tissues; pyridoxal and pyridoxamine occur in plant tissues. Together these three forms of the vitamin are of vital importance in the body for the synthesis of pyridoxal 5-phosphate which acts as coenzyme to amino

transferases, facilitating more than 60 amino group transfers and other reactions, including formation of neurotransmitters. The RDA is 1–3 mg but may increase on a high protein diet. Good sources are yeast, liver, peanuts, bananas, grapes and pears, beef and fish.

Chromatographic analysis of the vitamin B₆ complex, including sample preparation and pre-TLC extraction, have been well reviewed. Separation of pyridoxine from other water-soluble vitamins in pharmaceutical preparations can be improved by impregnating silica gel plates with zinc acetate to provide a self-indicating system after separation. Impregnation of plates with hexadecyltrimethylammonium bromide has similarly been used to improve the TLC analysis of vitamin B₆ in foods. Postaire has reported better separation and resolution of B₆ from other compounds using the overpressure layer technique than by HPTLC.

Cobalamin (Vitamin B₁₂)

Vitamin B₁₂ is the generic name for a group of vitamins known as cobalamins. The basic molecule consists of a corrin ring enclosing a central cobalt atom subtending axial ligands which determine the form and function of each individual cobalamin. Cyanocobalamin (CNCbl) was the first form of the vitamin isolated in 1948, independently by two groups. Both relied heavily on chromatography for the final separation and purification of CNCbl. Its complex three-dimensional structure was elucidated in 1956 by Dorothy Hodgkin using elegant X-ray crystallographic techniques.

The cobalamin molecule can only be synthesized by microorganisms, but all mammalian cells are equipped to covert the vitamin into its coenzymes. Cobalamin is without known function in plants and, if present, is only associated with the metabolic activity of microorganisms. Hence, unlike folate, dietary sources of the vitamin are exclusively animal in origin and include fish, meat – particularly liver and kidney – eggs and milk. Cobalamin is acid- and heat-stable but, like other hydrophilic vitamins, is destroyed by exposure to high pH. Notable features of cobalamin are that it is a much larger molecule (mol wt of OHCbl is 1346) than any other B-group vitamin and tissue levels are lower than any other, with total amounts in the body amounting to only a few milligrams. The low RDA of 1–2 µg is a reflection of the efficient means employed by the body to retain the vitamin. The low tissue levels of cobalamins naturally cause analytical problems and this has led to the development of enhanced methods of detection, discussed below.

Figure 2 Photolysis of methylcobalamin (MeCbl) in extracts of normal human plasma exposed to daylight. Most of the MeCbl was converted to hydroxocobalamin (OHCbl) in 2 min.

In humans, the two coenzyme forms of vitamin B₁₂ are adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl) and each is required in specific reactions involving, respectively, isomerization and transmethylation. Both coenzymes are very light-sensitive and are readily converted to hydroxocobalamin (OHCbl) by exposure to white light, as may be demonstrated (Figure 2). MeCbl was first synthesized in the laboratory by Lester Smith and detected in human plasma by Lindstrand in 1963 as an unidentified zone on paper chromatograms. Using large quantities of liver, this compound was isolated using chromatographic methods and characterized as MeCbl.

The bulk of cobalamin in the body occurs as AdoCbl in cells and MeCbl in plasma, but other forms detected include OHCbl, CNCbl and suphitocobalamin, which may be a breakdown product of glutathionylcobalamin, possibly an important metabolic intermediate. A variety of adsorbents may be used for cobalamin TLC but none has been found to better a mixed layer of Whatman CC41 microgranular cellulose and silica gel G (Figure 3). A sensitive two-dimensional TLC method has been developed which allows small blood and tissue samples to be used (Figure 4) to investigate cobalamin metabolism in health and a wide range of diseases, including cobalamin deficiencies and genetic errors of B₁₂ metabolism. The sensitivity of the method relies on the bioautography organism which is a selected strain of *Escherichia coli*, which has a cobalamin growth response down to 1–2 pg. Growth zones are

Figure 3 Separation of an aqueous mixture of four cobalamins by TLC on a gradient layer of cellulose (CC41) and silica gel (SGG), showing the influence of varying adsorbent mixtures on separation of the cobalamins. The mobile phase was butan-2-ol-water-0.880 ammonia (75 : 25 : 2).

Figure 4 Separation of cobalamins extracted from normal human plasma. The adsorbent was cellulose CC41-silica gel G (3 : 1) developed first in butan-2-ol-water-0.880 ammonia (75 : 25 : 2) and second, in water saturated with benzyl alcohol. The second development was at right angles to the first, after air-drying the plate. Extraction and chromatography were in darkness or by red light. Cobalamin zones were detected bioautographically by over-layering the chromatogram with agar seeded with a cobalamin-sensitive *Escherichia coli* mutant and a tetrazolium growth indicator. The 'sandwich' was incubated at 35°C for 18 h. Methylcobalamin (MeCbl) is the main form present in healthy subjects, with smaller amounts of adenosylcobalamin (AdoCbl) and hydroxocobalamin (OHCbl).

enhanced by inclusion of 2,3,5-triphenyltetrazolium chloride in the agar medium which is converted to the red dye fomazan during growth of the organism. The red zones corresponding to cobalamins separated on the TLC plate are then scanned by densitometer or computer and quantitated. A 10–100-fold increase in sensitivity is gained if radiolabelled cobalamins are separated and the bioautogram growth zones excised and their radioactivity measured.

Folic Acid

Folic acid (pteroylglutamic acid) and related compounds are present at high concentrations in liver, but spinach, broccoli, peanuts and fresh fruit are also good dietary sources. Foliates are important for the synthesis of tetrahydrofolate, which is important with cobalamin for a series of 1-carbon transfer reactions leading to DNA synthesis, failure of which leads to megaloblastic anaemia.

Chromatographic analysis of folate compounds including methotrexate and other antifolates has been reviewed. Process impurities in the reduced folate compound leucovorin calcium may be monitored using a TLC method with fluorescence detection. An overpressure layer TLC procedure (OPLC) has been used to improve the separation of folic acid from other water-soluble vitamins with good recovery and resolution. The method uses silica gel layers developed in butan-1-ol-pyridine-water (50 : 35 : 15) at a rate of 0.25 mL min⁻¹ for baseline separation. Quantitation is achieved without derivatization.

Biotin

Good sources of biotin are liver, pork, nuts, chocolate, pulses, cereals and royal jelly; biotin is widely distributed among all types of food and dietary deficiency is rare. However, biotin is inactivated by avidin, which is present in raw egg white, and severe eczema has been reported from this type of deficiency. This does not arise if cooked eggs are included in the diet, since heat deactivates avidin. Biotin acts as coenzyme to carboxylase enzymes, for example in the catabolism of propionate to methylmalonate. Biotin is stable in acid and neutral solutions and hence may be extracted at low pH before chromatography.

Biotin is separable from other water-soluble vitamins by TLC on silica gel or cellulose layers developed in neutral or acidic butanol–water mixtures. Various detection reagents have been used for biotin, including iodine vapour, 1% potassium permanganate, 1% dimethylaminobenzaldehyde in hydrochloric acid and *p*-dimethylaminocinnamaldehyde in a mixture of methanol and sulfuric acid, which is specific for biotin, yielding intense orange zones with an absorbance maximum at 533 nm. More recently, TLC, HPTLC and OPLC techniques have been compared, using five different mobile phases. Biotin tends to be resolved poorly from pantothenic acid by HPTLC but this is improved by OPLC, although in the systems investigated this led to less than perfect separation of biotin and folic acid.

Ascorbic Acid (Vitamin C)

Ascorbic acid occurs abundantly in fresh fruit, especially blackcurrants, citrus fruit and strawberries, and in most fresh vegetables; good sources are broccoli and peppers. It is destroyed by heat and is not well stored in the body. Ascorbic acid is a good reducing agent and facilitates many metabolic reactions and repair processes.

In pharmaceutical preparations and fruit juices, ascorbic acid is readily separated from other compounds by TLC on silica gel and quantitated directly by absorption at 254 nm. Serum and plasma may be deproteinized with twice the volume of methanol or ethanol. Various ascorbic acid compounds in plant extracts and foods have been separated on cellulose layers and detected by spraying with 2,5-dichlorophenol indophenol. Heulandite, a natural zeolite (particle size 45 µm) has successfully been employed as an adsorbent and ascorbic acid and other hydrophilic vitamins have

separated within 5 cm by ascending chromatography in dimethylformamide. HPTLC and OPLC methods have been developed to improve the separation of ascorbic acid from other water-soluble vitamins, with some success.

Conclusion

TLC is a flexible and well-established technique for the separation of water-soluble vitamins, limited only by the stability of the compounds to be separated, the resolving power of the TLC system and the sensitivity of the detection method. In complex biological systems these factors assume greater importance as vitamin concentrations are lower and metabolites may interfere with the separation. A preliminary extraction step or use of a short clean-up column can help remove salts and other interfering substances and may increase the concentration of vitamins to be chromatographed. Recovery experiments will monitor any selective losses at this stage.

The introduction of HPTLC and OPLC with optimized solvent systems has undoubtedly increased the resolving power for a number of vitamins. Gradient or two-dimensional TLC can increase this still further. Ultimately, it is the means of detection which determines the sensitivity of the system. Fluorimetry has become the method of choice for those vitamins forming fluorescent derivatives, but there are alternatives. One is to overlay the chromatogram with an agar medium seeded with a microorganism whose growth is sensitive to the vitamin. This can detect as little as a few pg of the vitamin. Even higher sensitivity can be achieved using radioactive vitamins detected autographically or with phosphorimagers. In future, the development of an immunoassay technique similar to Western blotting is likely to allow the most sensitive quantitation of vitamins separated by HPTLC.

VOLATILE ORGANIC COMPOUNDS IN WATER: GAS CHROMATOGRAPHY

Introduction

An important class of substances for which it is increasingly necessary to analyse in environmental waters comprises a wide range of volatile organic compounds (VOC). These include aromatics such as methylbenzene (toluene) and the dimethylbenzenes (xylenes), and the environmentally persistent halogenated solvents such as tetrachloromethane and trichloroethene. Many of these compounds are finding their way onto national and international lists of proscribed or regulated compounds, and as a result there is a requirement for robust methods of analysis to monitor both the

environment itself and potential sources of discharge to it.

In the aqueous environment, there are a number of sample types that an analyst may be required to examine, each presenting their own problems and challenges and requiring slightly different analytical solutions. Drinking waters, for example, are a relatively straightforward matrix, often with a clearly defined quality standard imposed, such as the requirements of the European Union Drinking Water Directive (see Further Reading). River waters and marine waters may also be required to meet exacting environmental quality standards (EQS), which are frequently much lower than those set for drinking waters where the presence of haloforms, for example, is an accepted by-product of the disinfection process. Monitoring of wastewater effluents is fundamental to environmental quality management, since these are

a major source of VOCs in the environment. Such effluents are frequently complex mixtures of many different compounds present in a wide range of concentrations, and as such offer special challenges to the analyst.

Quantitative analytical methods must therefore offer good precision and accuracy and be able to withstand the rigorous inspection required by the legislative environment, in order to demonstrate satisfactory compliance with the regulations.

This article discusses some of the methods available for the analysis of VOCs in these matrices and is illustrated with examples taken from routine drinking water and wastewater quality analysis. The chromatograms are reproduced here by courtesy of North West Water Laboratory Services.

Sampling Techniques

The first stage of any analysis, whether carried out in the field or remotely in the laboratory, is the collection of a representative sample and the preservation of that sample intact until it reaches the analyst. Without doubt the best approach is to sample straight into the container to be used for the analysis, but this may present logistical problems with handling either very small containers or carrying out precise measurements of volume. It is easy enough to do this in a clean, well-equipped laboratory, but it becomes a much more challenging task on a cold, wet river bank or windswept beach!

The problem is that with the analytes being so volatile, their concentration in the matrix can change significantly between sampling and analysis if the sample is not correctly taken. One method widely used with good results is to use a pre-cleaned screw-cap septum vial, made from borosilicate glass and of around 20 or 40 mL capacity. The vial is rinsed several times with the sample before being filled so that the meniscus stands proud of the brim. A thick septum faced with polytetrafluoroethylene (PTFE) is then slipped sideways over the top of the vial, ensuring that no air bubble remains trapped within, and the septum cap is then firmly screwed down, sealing the sample in the vial. A vial with a leaking seal will obviously cause sample to be lost, but will also allow preferential evaporation of VOCs. Similarly, a vial containing an air bubble will also damage sample integrity by allowing dissolved VOCs to equilibrate between the aqueous and vapour phases. Any subsequent sample taken from the vial for analysis will therefore contain a *lower* concentration of VOCs than the original.

Use of a septum will allow the withdrawal of a subsample from the vial, using a syringe and an air bleed

Table 1 Common options for the analysis of VOCs

<i>Introduction</i>	<i>Separation</i>	<i>Detection</i>
Solvent extraction	GC	FID
Direct aqueous injection		ECD
Headspace		MS
Purge-and-trap		ELCD PID

Note: FID, flame ionization detector; ECD, electron-capture detector; MS, mass spectrometry; ELCD, electrolytic conductivity detector; PID, photoionization detector.

needle, without opening it and risking the possible loss of volatiles. Similarly, a suitable extraction solvent may be added by a displacement technique. Some laboratories use these approaches; others will open the vial and rapidly transfer the required volume to another closed container. Either way, taking further subsamples should be avoided, as the concentration of VOC in the sample will already have begun to change. Further information on sample collection is to be found in a 1987 HMSO publication.

Methods of Analysis

Modern capillary gas chromatography (GC) lends itself particularly well to the low-level analysis of VOCs, offering a good separation of the analytes and high sensitivity. There is a variety of sample introduction techniques in common use and a wide choice of columns is available to the analyst. Several different detector systems can be used, dependent on the analytes and the sensitivity and specificity required.

The actual method of analysis chosen will depend on several factors. These include the analytes themselves, the sample matrix, the resources available to the analyst and the level of confidence required in the results. For example, an analyst interested in a rough-and-ready assessment of the presence of aromatic solvents at levels in excess of 1 mg L⁻¹ might choose to use direct aqueous injection (DAI) with a flame ionization detector (FID) as the simplest way of obtaining the information required. Conversely, an analyst investigating a complex industrial wastewater and providing evidence for prosecuting an illegal discharge may prefer the precision of a headspace sample introduction technique and the confirmatory information which may be obtained by using a mass spectrometer (MS) as a detector. The commonest options are set out in Table 1.

Sample Introduction Techniques 1: Solvent Extraction

Solvent extraction is a useful technique for dealing with relatively clean samples, such as drinking waters

Table 2 Solvent extraction performance data for selected compounds

Compound	Recovery (%)	RSD (%)	LOD ($\mu\text{g L}^{-1}$)
Trichloromethane ^a	85	6.1	0.19
Tetrachloromethane ^a	79	11.7	0.009
Tetrachloroethene ^a	104	3.1	0.012
Benzene ^b	105	nd	1.58
Methylbenzene ^b	99	nd	0.13

^aChlorinated compounds determined at a concentration of $2.5 \mu\text{g L}^{-1}$ (tetrachloroethene $5 \mu\text{g L}^{-1}$) with four degrees of freedom. 20 mL sample extracted with 2.5 mL petroleum ether 30–40°C. Analysis by packed column GC-ECD. From HMSO (1987).

^bAromatic compounds determined at a concentration of $10 \mu\text{g L}^{-1}$. 1 L sample extracted with 10 mL pentane, cleaned up with florisil and concentrated to 1 mL. Analysis by $50 \text{ m} \times 0.2 \text{ mm}$ OV-1 capillary column with FID. From HMSO (1987). RSD, relative standard deviation; LOD, limit of detection; nd, not determined.

or high-quality river waters. The pentane or hexane extraction solvent may be added to the sample vial by displacement, as described above, and the vial is then shaken or rolled for up to 30 min. A sample of the solvent may then be withdrawn – again without opening the vial – and analysed by GC using conventional sample inlet techniques such as split/splitless or on-column injection. Typical sample/solvent ratios of between 5:1 and 20:1 give some sample pre-concentration, but the injection volume of around 1–2 μL restricts ultimate sensitivity.

The technique is well-suited to the analysis of chlorinated hydrocarbons, using an electron-capture detector (ECD), but may also be used in conjunction with most other types of detector, including mass spectrometers. Its main drawback is the time and effort required to carry out the extraction. Some performance data are listed in Table 2.

Sample Introduction Techniques 2: Direct Aqueous Injection

Perhaps the simplest of all sample introduction techniques, direct aqueous injection has been the subject of several papers. It has a number of advantages, not the least of which is convenience: samples collected in the manner described above require no further handling between collection and final analysis. As the name of the technique suggests, a 1 μL aliquot of sample is taken from the vial and injected directly into the instrument, using either an on-column or split/splitless injector.

This technique has been applied to the analysis of trihalomethanes and is said to be reliable and offers good precision and recoveries. Recoveries of 100% and peak area standard deviations of between

1.9 and 5.2% with approximately 14 degrees of freedom at the $10\text{--}100 \mu\text{g L}^{-1}$ level for the four chlorine- and bromine-containing trihalomethanes have been quoted. This compares with recoveries of between 60 and 90% for pentane extraction. The technique has been shown to be applicable to other chlorinated hydrocarbons, including 1,1,1-trichloroethane and tetrachloromethane.

The technique certainly works well with small numbers of samples, but experience in a laboratory handling upwards of 30 analyses daily suggests that the robustness of the analytical system becomes an important factor. Passing relatively large quantities of water vapour through an ECD shortens its useful life, and therefore the alternative inlet techniques described here are to be preferred where large numbers of samples are involved.

Another potential problem with the technique is that there is no initial clean-up of the sample and it is therefore only appropriate for relatively clean samples such as drinking waters. With other sample matrices there is a risk that significant quantities of nonvolatiles (including inorganic salts) can build up at the front of the column, reducing its life; similarly, the presence of less-volatile contaminants remaining on the column may interfere with subsequent analyses.

Despite this, DAI may be used successfully where a minimum effort, rough screening method is required, e.g. for an industrial wastewater. The use of an FID allows other, nonhalogenated compounds such as aromatics to be detected and estimated at milligram per litre levels. This analysis may be sufficient to meet some needs, but could also be used as a pre-screening technique to identify appropriate dilution factors for headspace or purge-and-trap analysis. An example of a chromatogram of a standard solution of aromatic compounds in water is shown in Figure 1.

Figure 1 Aromatic compounds in water by DAI. Conditions: 1 μL injection; injector temperature 230°C ; $30 \text{ m} \times 0.25 \text{ mm}$ DB-1 column; temperature program 70°C , hold 2 min $\rightarrow 90^\circ\text{C}$ at $20^\circ\text{C min}^{-1} \rightarrow 260^\circ\text{C}$ at $35^\circ\text{C min}^{-1}$, hold 5 min; FID temperature 280°C . Chromatogram shown is from a standard solution in water containing 10 mg L^{-1} each compound.

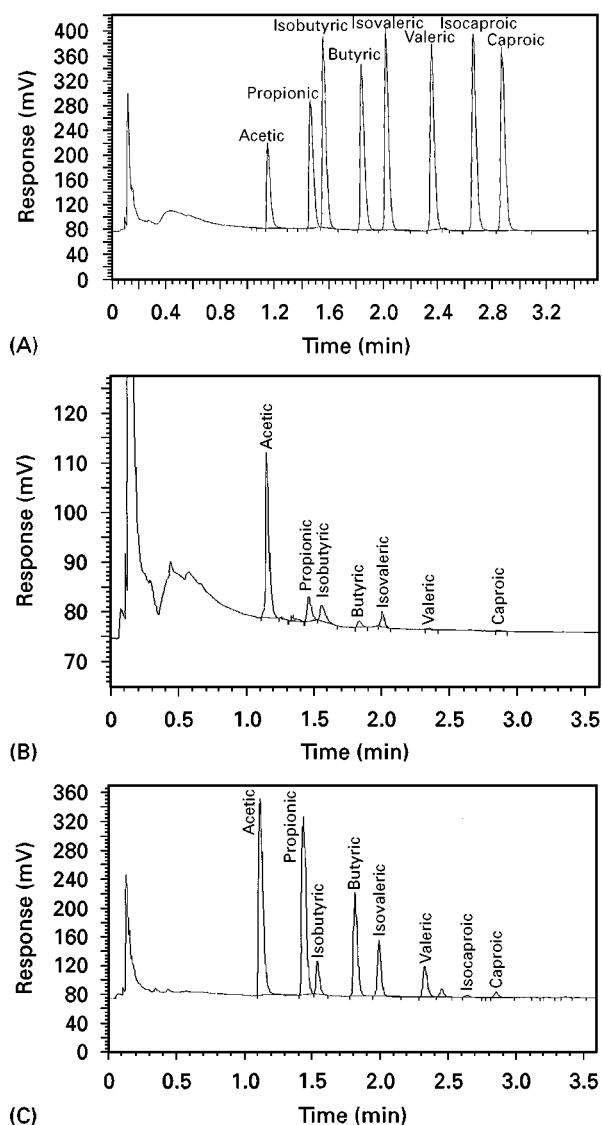

Figure 2 Analysis of VFA in sewage sludge supernatant water by DAI. Conditions: 1 μL 20 : 1 split injection; injector temperature 250°C; 12 m \times 0.53 mm BP-21 column; temperature program 60°C \rightarrow 250°C at 20°C min⁻¹, hold 3 min; carrier gas, nitrogen 3 mL min⁻¹; FID temperature 300°C. (A) Chromatogram shown is from a standard solution in water containing approximately 800 mg L⁻¹ each compound. (B) VFA in digested sludge. Acetic acid concentration 100 mg L⁻¹; others < 10 mg L⁻¹. (C) VFA in a partially digested sludge. Acetic acid concentration approximately 800 mg L⁻¹.

Difficult-to-extract analytes such as alcohols, ketones or volatile fatty acids (VFA) may also be estimated by this technique (Figure 2). A specific application is the analysis of VFA in sewage sludge, the results of which are used to monitor the performance of sludge digesters in wastewater treatment plants. Samples of sludge are centrifuged and the supernatant water filtered through a 1 μm membrane, in order to prevent particulate matter blocking either the injection

syringe needle or the capillary column itself. Acidified with phosphoric or formic acid, the samples are then analysed by direct aqueous injection GC-FID. The analytical range required of the application is typically 1–1000 mg L⁻¹ for each compound, although ethanoic (acetic) acid will predominate in samples from a stable digester.

A simple packed column application of direct aqueous injection is the analysis of methane in water. A 1 μL sample is injected directly onto a 1 m ChromosorbTM 101 column for isothermal analysis at 70°C, with an FID. Calibration is normally carried out using a standard gas mixture.

Sample Introduction Techniques 3: Headspace Analysis

Headspace analysis is a clean, reliable method of introducing volatile analytes to a GC column, and is especially useful where complicated matrices such as industrial wastewaters containing many other contaminants must be analysed. Involving the analysis of just the *vapour* above a sample of water, the method provides instant clean-up by ensuring that only volatile materials are introduced into the GC sample inlet, resulting in a clean chromatogram and enhanced column life.

The technique is a practical application of Henry's law, which states that 'the vapour pressure of a solute is proportional to the amount of solute present in a solution at equilibrium with its vapour'. Thus if the concentration of an analyte in the vapour phase can be measured, it can be correlated by a suitable calibration with its concentration in the sample.

The two methods of introducing samples to the GC are known as *static* and *dynamic* headspace. In the former, the vapour in equilibrium with the sample in a vial is analysed, usually at an elevated temperature; in the latter the vapour is first enriched by actively purging the sample with an inert gas.

Given that the solubility of gases decreases with increasing temperature, raising the temperature of the sample will favour the vaporization of the analytes, enriching the headspace, and this effect is used to enhance analyte recovery. It does mean, however, that temperature must be rigorously controlled both during analysis and from sample to sample, if reproducibility is to be assured.

Static headspace Samples may be collected for this analysis in two ways. A vial can be filled as described previously, or a fixed amount (typically 5–10 mL) of sample may be accurately measured and sealed – with an internal standard, if one is to be used – in a vial of about 20–25 mL capacity, which is to be used for the

analysis. The latter option would allow the sample to be presented to the instrument unopened, minimizing the requirement for sample preparation in the laboratory, but practical considerations in the field mean that the former is often preferred.

Sealed in its headspace vial, the sample is placed in a thermostatted heater and allowed to equilibrate with the air space above it. Some headspace sampling devices will also agitate the sample to accelerate this equilibration. Once equilibrium is established, the vial is pressurized with carrier gas passing through a sampling needle penetrating the septum. On reaching the required pressure, the flow is reversed, carrying sample vapour to the GC inlet. The volume transferred is controlled either by reversing the flow for a fixed time or by the use of a sample loop. The liquid sample therefore does not come into contact with any part of the GC itself.

Calibration of the system is carried out by preparing standard solutions of the analytes of interest in water, and treating them in exactly the same way as samples, sealing the same volume in a vial and subjecting them to the whole procedure described above. Key to the process is consistency: each sample and standard must be treated exactly alike, and automated headspace samplers facilitate this. In order to achieve reproducible results, it is not even necessary for the samples to achieve equilibrium; providing they are consistently treated, i.e. by equilibrating at exactly the same temperature and for the same length of time, reproducibility is assured.

A suitable internal standard can be added to the headspace vial before sealing and then used either directly to calibrate the individual analysis or to aid an external calibration process.

The technique has a good linear range and sensitivity and provides a robust and reliable method of introducing both clean and dirty water samples to a GC with very little sample preparation (Table 3). As might be expected, attainable recoveries measured against standard solutions are close to 100% and

Table 3 Headspace performance data for selected compounds

Compound	Recovery (%)	RSD (%)	LOD ($\mu\text{g L}^{-1}$)
Trichloromethane	99.95	3.4	1.42
Tetrachloromethane	98.30	4.18	0.04
Tetrachloroethene	96.84	4.43	0.44

Data determined at a concentration of $122 \mu\text{g L}^{-1}$ (trichloromethane); $3 \mu\text{g L}^{-1}$ (tetrachloromethane); and $10 \mu\text{g L}^{-1}$ (tetrachloroethene) with approximately 17 degrees of freedom. 5 mL sample equilibrated for 5 min at 80°C . Analysis by $30 \text{ m} \times 0.53 \text{ mm}$ DB-624 capillary column GC-ECD. Data provided by North West Water Laboratory Services.

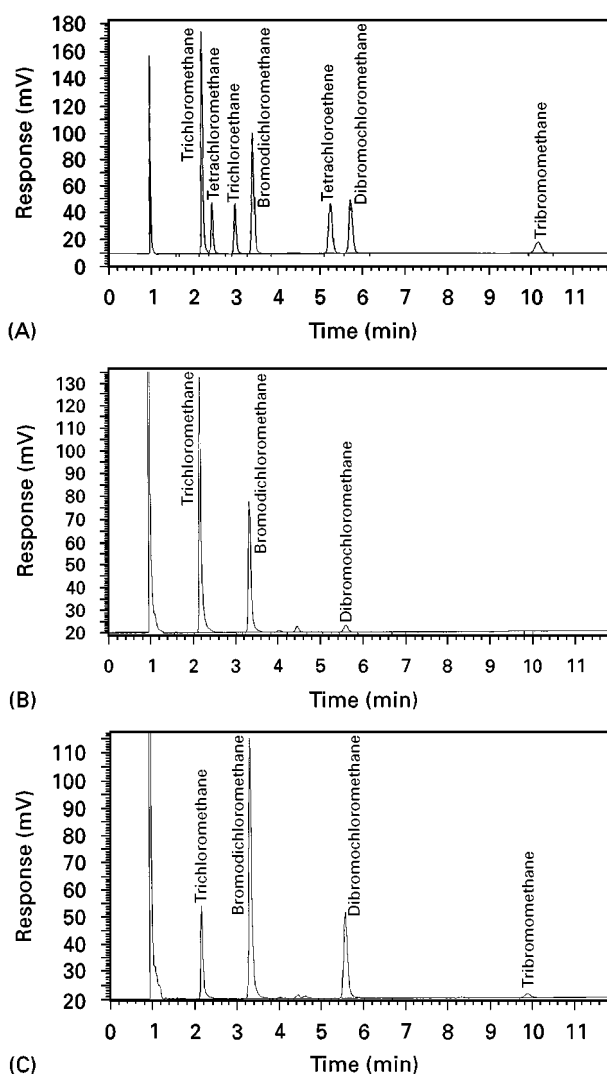

Figure 3 Analysis of trihalomethanes and chlorinated hydrocarbons in drinking water by headspace GC-ECD. Conditions: 5 mL sample, equilibrated for 10 min; $30 \text{ m} \times 0.53 \text{ mm}$ DB-624 column; isothermal at 80°C . ECD temperature 250°C ; carrier gas: nitrogen 7.5 mL min^{-1} . (A) Chromatogram shown is from a standard solution in water containing $91.5 \mu\text{g L}^{-1}$ trichloromethane (highest concentration component) and $2 \mu\text{g L}^{-1}$ tetrachloromethane (lowest). (B) Trihalomethanes in drinking water derived from a surface source. Concentrations: trichloromethane $63 \mu\text{g L}^{-1}$; bromodichloromethane $7 \mu\text{g L}^{-1}$; dibromochloromethane $1 \mu\text{g L}^{-1}$. Note the almost total absence of other chlorinated hydrocarbons. (C) Trihalomethanes in blended drinking water derived from surface and underground sources. Concentrations: trichloromethane $18 \mu\text{g L}^{-1}$; bromodichloromethane $12 \mu\text{g L}^{-1}$; dibromochloromethane $2 \mu\text{g L}^{-1}$; tribromomethane $< 2 \mu\text{g L}^{-1}$. Note the reduced concentration of chlorinated compounds and the increase in brominated compounds.

interferences and column degradation are minimized. It may be used with any detector type, including mass spectrometers. An example of the analysis of trihalomethanes and chlorinated hydrocarbons in drinking water is shown in Figure 3.

Absolute recoveries are dependent on equilibration time and temperature. Increasing the equilibration time to the point where the sample and its vapour are fully equilibrated will maximize recovery; raising the temperature will increase the partial pressure of volatile compounds in the headspace. Systems typically operate at temperatures of up to 80°C: any higher and the increased vapour pressure of the water matrix itself interferes, negating the benefits.

One drawback is the inability to reanalyse samples, because once a vial has been subsampled, the integrity of the sample itself is destroyed and equilibration with the new headspace will alter the composition of the sample. This means that a subsequent repeat analysis cannot be carried out if confirmation of a result is required: a fresh sample must be collected. Although this may present a problem to the environmental analyst, a technique known as 'multiple headspace extraction' (MHE) has been described (see Further Reading) where a sample is equilibrated with successive volumes of gas. Analysis of each successive headspace volume will allow the distribution of the analytes to be determined, providing a measure of an important physical property. Headspace analysis has been used for this purpose almost since it was first developed.

The extrapolation of MHE data to the 'zero equilibration' level provides a measure of the original concentration of an analyte. This may be particularly useful in situations where for some reason it is not possible to calibrate the analytical system with either the analyte or matrix of interest, or where an 'absolute' recovery must be determined.

Dynamic headspace Dynamic headspace or purge-and-trap sampling is an effective way of achieving high sensitivity in the analysis of VOC. This is particularly important in the analysis of environmental samples for comparison with stringent EQS, which frequently test the limits of analytical methodology.

Unlike static headspace, where the sample is simply allowed to equilibrate, in purge-and-trap the sample is purged with an inert gas (usually helium) in order to drive the volatiles out into the vapour phase. The vapour is then caught in a cold trap or adsorbed on an appropriate support before being thermally desorbed and passed to the GC inlet. The method retains the advantage of the headspace technique in terms of presenting a clean sample to the GC, but potentially offers much greater sensitivity (Table 4).

Whilst the technique has the ability to improve sensitivity, the overall range of an analysis may not be increased, since this is dependent on the dynamic range of the detector. This means that with the general tendency to analyse suites of compounds to-

Table 4 Purge-and-trap performance data for selected compounds

Compound	Recovery (%)	RSD (%)	LOD ($\mu\text{g L}^{-1}$)
Trichloromethane	94.10	3.80	0.002
Tetrachloromethane	nd	nd	0.004
Tetrachloroethene	98.80	1.30	0.005
1,2-Dichlorobenzene	77.70	8.50	0.020
Methylbenzene	99.11	0.77	0.001
1,2-Dimethylbenzene	98.38	1.46	0.004

Recovery and RSD data determined at a concentration of $4 \mu\text{g L}^{-1}$ with approximately two degrees of freedom. 25 mL sample purged at 35°C with helium, 50 mL min^{-1} for 10 min. Analysis by packed column GC-FID. From Driss and Bouguerra (1991). LOD, limit of detection. 5 mL sample purged with helium, 40 mL min^{-1} for 2 min. Analysis by $60 \text{ m} \times 0.53 \text{ mm}$ DB-624 capillary column GC with electrolytic conductivity detector and photo-ionization detector. From Mehran, Nickelsen, Golkar and Cooper (1990) *Journal of High Resolution Chromatography* 13: 429–433.

gether, those compounds for which low limits of detection are required can be analysed satisfactorily, but those present in higher concentrations in the same sample may well exceed the range of the detector! For example, purge-and-trap GC-MS analysis of some drinking waters easily achieves the required limit of detection of $0.3 \mu\text{g L}^{-1}$ for tetrachloromethane, but exceeds the linear range of the detector for the trichloromethane present in a much higher concentration.

The optimization of a purge-and-trap method has been examined and both purge gas volume and temperature have a significant effect on analyte recovery. Keeping the purge gas flow rate constant, but extending the purge time from 10 to 20 min, greatly enhanced the recoveries of all the analytes examined, although the recoveries of compounds with a higher solubility in water (e.g. tribromomethane) were still poor. Difficulties have been reported with the use of very short purge times: 1 min gave rise to reproducibility problems due to the mode of operation of the equipment, whereas 2 min resulted in an acceptable performance and a much faster method. Extended purge times may risk compromising recoveries of highly volatile compounds, since these can be purged efficiently in a short time. Recovery is then dependent on the efficacy of the trap in retaining them until the chromatographic separation is ready to begin.

Elevated temperatures also speed recovery. Results obtained from purging for 20 min at 25°C have been found to be comparable with those from a 10-min purge at 40°C. The disadvantage of using a higher temperature is that more water vapour is carried over into the analytical system. Without effective control

Table 5 Effect of purge time and temperature on recovery of selected compounds

Compound	Recovery (%)			
	10 min purge	20 min purge	30°C	40°C
Trichloromethane	78.06	91.81	82.01	87.63
1,2-Dichloroethane	60.55	88.10	62.48	64.75
Tetrachloroethene	98.03	99.10	97.94	100
1,2-Dichlorobenzene	59.86	66.82	60.94	65.41
Methylbenzene	85.73	93.12	88.63	94.05
1,2-Dimethylbenzene	81.86	84.28	84.99	89.66

Data determined at a concentration of $4 \mu\text{g L}^{-1}$ with approximately two degrees of freedom. 25 mL sample purged with helium, 50 mL min^{-1} 10/20-min purge data determined at 25°C . Temperature data determined with a purge time of 10 min. Analysis by packed column GC-FID. From Driss and Bouguerra (1991).

this will interfere with the analysis – particularly with moisture-sensitive equipment such as ECD or mass spectrometers. For this reason, purge temperatures significantly greater than 40°C are not widely used. Table 5 shows the effect of purge time and temperature on the recovery of selected compounds.

Waters containing detergents or other foaming agents may prove difficult to analyse effectively by this technique. It is, however, suitable for use with most types of detector.

Matrix Modification

The use of matrix modifiers is common practice in water analysis, and they are often used to enhance the performance of some methods for the analysis of VOC – in particular the headspace and purge-and-trap methods. The addition of modifiers such as sodium chloride or sodium sulfate to samples prior to analysis will – by modifying the activity coefficient of the VOC solutes and the vapour pressure of the solvent – enhance the relative concentration of the analyte in the headspace above the sample. This effect is most noticeable for the less soluble or less volatile compounds such as the dimethylbenzenes or the dichlorobenzenes, although it may be of limited use with other compounds, such as trichloromethane, where

recoveries may readily be optimized by temperature control.

Although the effect may be used to improve the performance of a method, it is important to remember that the samples themselves may be subject to some variability. Table 6 provides the evidence to show why a seawater sample could not be analysed using a method set up and calibrated for use with drinking water, or vice versa: the performance of the method will differ significantly between the two matrices. For the same reason, it is important that the ionic strength of both samples and standards is consistent. If there is any doubt then an excess of salt (e.g. around 2 g mL^{-1}) should be added to all samples and standards to ensure consistency.

Analytical Columns

Today, most applications for VOC analysis use capillary columns, the length and film thickness of which will depend on the complexity of the analysis. Up to about 20 compounds can be satisfactorily resolved by a 25–30 m column in about 10 min, whereas a 50–60 m column is more appropriate for samples containing 60 or more analytes, taking 30 min to 1 h to achieve an acceptable separation.

Although the superior resolution of the capillary column means that most separations can be achieved using ‘standard’ nonpolar or moderately polar phases such as DB-1 from J & W or BP-5 from SGE, there is an increasing number of columns tailored for specific analyses. These include J & W’s DB-624 phase, designed to substitute for the packed column specified in US Environmental Protection Agency (US EPA) method 624, for purgeable organic compounds. Such columns are designed to optimize the separation and the time required for the analysis of the compounds of interest.

The direct aqueous injection technique requires the use of bonded-phase columns to ensure that the water passing through it does not destroy the column.

Table 6 Effect of ionic strength on recovery of selected compounds

Compound	Purging efficiency		
	0% NaCl	10% NaCl	20% NaCl
Trichloromethane	83.63	93.98	98.52
1,2-Dichloroethane	63.2	67.97	76.17
Benzene	90.12	97.22	99.50

1,2-Dimethylbenzene	86.43	96.72	98.91

Purge-and-trap recovery data determined at a temperature of 35°C . From Driss and Bouguerra (1991).

Detectors

Perhaps the commonest detectors used for VOC analysis in the environmental industry are the ECD and the mass spectrometer, primarily because of the keen interest in levels of organochlorine compounds in the environment. However, the FID also finds application in the analysis of hydrocarbons – including aromatics – providing reliable detection and sensitivity down to around $100 \mu\text{g L}^{-1}$ without sample pre-concentration. It may also be used with mixtures of hydrocarbons and some chlorinated solvents, and although limits of detection for the latter are relatively high, the robustness of the detector may make it an appropriate choice for the analysis of an industrial wastewater, for example. As previously described, the FID can be used for the analysis of relatively high concentrations of VOCs by the direct aqueous injection technique.

Where low levels of halogenated solvents are to be determined, by far the best option is to use an ECD, which has a high specificity and sensitivity for many halogenated compounds. This will work with all of the sample introduction techniques previously described, although complex industrial wastewaters may contain compounds that contaminate the detector. In such cases, selective introduction techniques such as headspace or purge-and-trap are to be preferred, as these will eliminate or substantially reduce the contaminants introduced to the system.

When a wide-ranging screen coupled with specificity and reasonable sensitivity is required, then a mass spectrometer may be used. Small bench-top instruments are increasingly found in environmental laboratories, and many are employed in just this kind of activity, coupled to headspace GC systems. Such a configuration provides a good response to a variety of compound classes, is robust enough to handle samples of badly contaminated industrial wastewaters, and yet has sufficient sensitivity to analyse clean river waters to the levels required by most EQS. Additionally, the ability to produce a recognizable mass spectrum lends confidence to the identification of analytes. This is of particular importance when collecting evidence for the prosecution of an illegal discharge. Examples of analysis of chlorinated and aromatic hydrocarbons by headspace GC-MS are shown in Figure 4.

Other detector types in use, particularly in the USA, include the electrolytic conductivity detector (ELCD) and the photoionization detector (PID) specified in some EPA methods. The latter can be up to a hundred times more sensitive than a FID when used for the analysis of some aromatic compounds, but in contrast to both the ECD and ELCD it will not detect the lighter haloalkanes such as those found in drink-

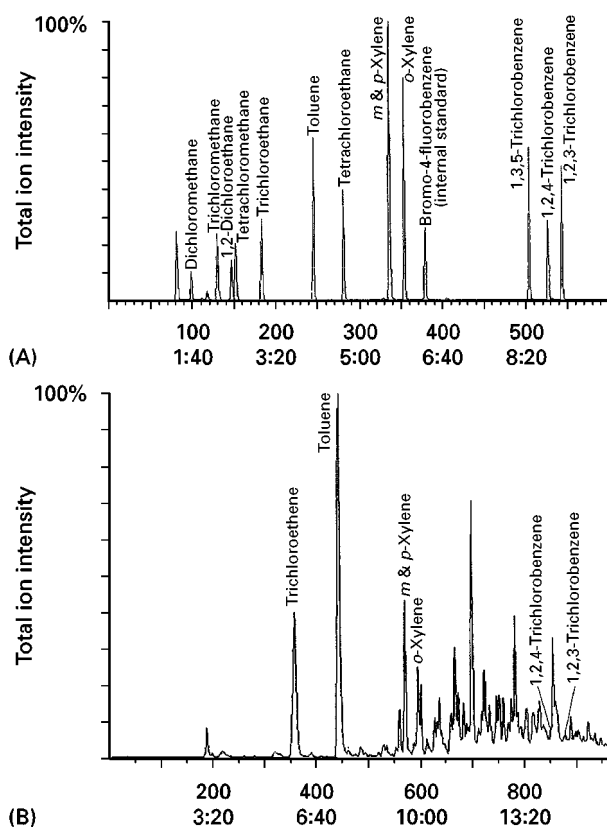

Figure 4 Analysis of VOCs by headspace GC-MS. Conditions: 5 mL sample, equilibrated for 10 min; 30 m \times 0.25 mm DB-5MS column; temperature program 40°C , hold 5 min \rightarrow 200°C at $15^\circ\text{C min}^{-1}$ \rightarrow 250°C at $50^\circ\text{C min}^{-1}$; carrier gas: helium 3 mL min^{-1} ; Ion TrapTM detection, EI mode, 1 s scan, mass range 45–220 amu. (A) Chromatogram shown is from a $100 \mu\text{g L}^{-1}$ standard solution in water. (B) VOCs in trade effluent from a road haulier's premises. Conditions as above except carrier gas approximately 1.5 mL min^{-1} . Approximate concentrations: trichloroethene $1150 \mu\text{g L}^{-1}$; toluene $1700 \mu\text{g L}^{-1}$; *m*- and *p*-xylenes $500 \mu\text{g L}^{-1}$; *o*-xylene $250 \mu\text{g L}^{-1}$; 1,2,4-trichlorobenzene $20 \mu\text{g L}^{-1}$; 1,2,3-trichlorobenzene $40 \mu\text{g L}^{-1}$. Other compounds, including the internal standard, are also present, but cannot be seen on this scale.

ing water. The convenience the ECD offers over the ELCD coupled with the greater specificity and sensitivity of the PID relative to the FID means that a useful application for the detectors in tandem is the analysis of both halogenated and aromatic compounds in the same sample.

Of course, providing the sample introduction technique is compatible (as indeed the headspace methods inevitably will be), any detector type can be used to meet the specific requirements of the analysis.

Conclusion

This article has summarized the main methods of analysing for VOC in common use today and

has briefly described some of the advantages and disadvantages of each. It is hoped that the data illustrating the performance of the methods will assist readers in selecting an appropriate technique for their own application.

It is difficult to see where VOC analysis will go in the future, although possible developments include the more widespread application of automation to the dynamic headspace technique, enabling the unattended analysis of large batches of samples. Continued development of membrane and other direct inlet techniques for mass spectrometry and the shrinking size and price of MS-MS instruments may ultimately render the time-consuming chromatographic separation itself superfluous, offering the prospect of analysis in seconds rather than tens of minutes. However, for the time being the availability of suitable membranes permitting the migration of VOC restricts the application of this technique.

The increasing sensitivity of detection systems could well prove to be of little benefit to the analyst, as it may only serve to encourage the setting of even lower quality standards!

Whatever happens with the equipment and methodology that is employed, it is clear that continued growth in legislation controlling these substances in the environment will lead to an ever-increasing workload for the analytical laboratory.

WATER TREATMENT

Overview: Ion Exchange

Mid Glamorgan, Wales, UK

Copyright © 2000 Academic Press

Introduction

Ion exchange resins are used for many water treatment applications. Of these applications, in terms of the volume of resins used, water softening and demineralization of water are the most significant. Water softening has been practiced commercially for a century or more, making use of a wide range of natural and synthetic products. As the variety of uses for purified water has increased, so has the need to soften and demineralize water. Demineralization has only been practiced since the discovery of synthetic anion exchange resins in the 1920s. Their usefulness increased greatly with the invention of strongly basic anion exchange resins, which can remove weakly acidic compounds such as silica and carbon dioxide, as well as mineral acids. This process of ion exchange can be used as a simple method to produce water of very high purity. In general, as industrial and domestic requirements have grown, specifica-

tions for water quality have become progressively more stringent, and regulations to enforce these have become more strict. Hence the choice of resin types for a particular application becomes increasingly complex.

Applications of Ion Exchange in Water Treatment

A wide variety of new water treatment applications employ ion exchange resins in limited volume and there is limited use in niche areas for many special resin types. However, reverse osmosis (RO) is increasingly being used instead of ion exchange where treated water quality requirements are not particularly high. The use of RO followed by an ion exchange polishing process is often used for the production of high purity water, for example in the manufacture of silicon chips for the computer industry. **Table 1** lists the major water treatment processes in which ion exchange resins are used.

Principles of Ion Exchange Applicable to Water Softening

The properties and theoretical principles of ion exchange resins are fully covered elsewhere. This article

Table 1 Major water treatment processes

<i>Process</i>	<i>Resins used</i>	<i>Significant property</i>	<i>Application areas</i>
Softening	SAC	Hardness selectivity	Domestic, industrial processes, food processing, etc.
Partial softening Dealkalization	WAC WAC	Temporary hardness removal and alkalinity removal	Potable water, beverage industry, industrial processes, laundry, glass washing
Demineralization	WAC, SAC WBA, SBA	Removal of cations Removal of anions	Industrial water processes Steam generation, food processing industry, process water for pharmaceutical use, etc.
Nitrate removal	SBA	Nitrate selectivity	Potable water, food and beverage processing
Metals removal	WAC chelate resins	Selectivity for heavy metals	Wastewater treatment
Sorption	Macronets WBA, SBA	Selectivity for organics	Organic scavenging

Key: WAC, weak acid cation resin; WBA, weak base anion resin; SAC, strong acid cation resin; SBA, strong base anion resin; chelate, chelating ion exchange resin; macronet, special resin with adsorption properties.

discusses only those principles that directly relate to operating performance of the ion exchange resins that are currently used in water treatment.

Ion Exchange Equilibria

Water softening is a very efficient process. Water containing hardness ions (calcium and magnesium) is passed through a cation exchange resin in the sodium form. In dilute solution, the hardness ions are selectively held:

$$K_{Na}^{Ca} = ([Ca_R]/[Na_R^2]) \times ([Na_S^2]/[Ca_S]) \times C_S/C_R \quad [1]$$

where K is a simplified selectivity coefficient describing the equilibrium. $[Ca]$ is the calcium concentration, $[Na]$ is the sodium concentration, and C is the overall ionic concentration. Subscripts R and S represent resin and solution phase, respectively. This equation takes no account of activity coefficients, but nevertheless can be used, certainly for comparative purposes, and usually gives fairly accurate predictions. Clearly the larger the value of K_{Na}^{Ca} , the greater the fraction of calcium residing in the resin phase. Tables of selectivity coefficients have been compiled for a wide variety of cations and anions.

Selectivity for Hardness in Softening and Resin Regeneration

The more dilute the ionic concentration, the higher the calcium (and magnesium) fraction in the resin phase, and the less calcium is needed in the solution phase to satisfy the equation. However, when considering regeneration, the ionic concentration in solution is much higher, so as C_S/C_R tends to a value greater than 1, so less calcium is needed in the resin phase to satisfy the equation. The poorer selectivity of the resin sites for calcium present in high ionic concentrations ensures that the regeneration stage is very efficient. The principle of this equation applies to all comparisons between monovalent ions such as sodium and divalent ions such as calcium. Since magnesium, the other main contributor to total hardness, is also divalent, the principles described apply equally to magnesium. In order that the regeneration process is reasonably efficient, there must be an excess of sodium ions.

Reverse Osmosis

One of the advantages of RO is that no regenerant chemicals are required. The disadvantages of RO is that capital costs are higher and pumping costs can also be high. In addition, the volume of the reject waste can be large, even though the ionic concentration within the reject is quite low. There is also a risk

of membrane fouling. Generally when the total dissolved solids (TDS) in the treated water are high, RO is preferred. However, as both processes are constantly changing in efficiency, the commercial breakeven cost point is constantly changing.

Water Quality and Regeneration Efficiency

Clearly the use of smaller quantities of regenerant would make the ion exchange softening process more efficient and competitive. It has been demonstrated that the ion exchange process must be carried out in a column if the efficiency is to be optimized. For example, regenerating calcium from a resin with sodium chloride solution simply by adding the regenerant to the resin while stirring in a beaker is very inefficient. It suffers from the disadvantage that all the calcium displaced from the ion exchange resin has the opportunity to re-enter the resin and re-occupy the ion exchange sites. On the other hand, in a column operation, the displaced ion is carried away, and cannot return to the same beads at the regeneration entry point. As more fresh regenerant is added this same principle applies to the exchange process further down the column. It has been shown that, as the regenerant contact time in the column was increased to 24 h or more, the efficiency of regeneration decreased to the point where some 25–30% fewer sites were regenerated with the same quantity of regenerant. The final lower value tended asymptotically to that obtained under batch equilibrium conditions.

Counterflow and Co-flow Regeneration

A second advantage of column operation is that those beads situated at the point of entry of the regenerant will come in contact with a vast excess of pure regenerant. This ensures that almost all of the hardness ions loaded in the previous cycle are carried away from that part of the resin bed. In a stirred batch system, the ratio of regenerant ions to hardness ions would be approximately equal in every bead, depending on the quantity and concentration of regenerant used. It follows that since the water being treated is in counterflow to that of the regeneration, this allows the treated water to pass the most highly regenerated and rinsed resin at the point of exit, thus ensuring near zero leakage of hardness. Of course, the resin bed must not be disturbed for this advantage to apply. In co-flow regeneration, any regenerant at the treated water outlet has previously been in contact with the ions to be removed, hence this part of the column is least efficiently regenerated. In the following exhaustion cycle the sodium in the water at the outlet can 'back-exchange' for the hardness residual at the column outlet. This results in a significant hardness leak-

age. To optimize the operating efficiency, the use of regenerant chemical should be cut to a minimum. This has the added advantage that less excess regenerant will pollute the environment. From the above arguments, it is easy to see why counterflow regeneration is more efficient.

Diffusion in the Regeneration Stage

Returning to eqn [1], it can be shown that reduction of the regenerant quantity to a minimum can create significant disadvantages in the softening process. When the regenerant enters the column, it will inevitably suffer some dilution with the water it displaces. As has already been explained, the lower the ionic concentration in solution, the higher the selectivity for the divalent hardness ions, so any dilution will reduce the efficiency of the regeneration process. However, this dilution at the start of the regeneration process is not a significant disadvantage, because the regenerant is in contact with resin heavily loaded with hardness ions and thus some of these ions are easy to remove. However, as the regeneration proceeds, the concentration of regenerant increases and the beads are increasingly invaded by sodium chloride. This is termed 'Donnan invasion'. In fact, the first molecule of sodium chloride is not effective in achieving any regeneration of divalent hardness because only one of the two hardness bonds is released. The positive charge of the single displaced calcium ion is satisfied with the negatively charged chloride ion.

where R is the matrix and functional group of the strong acid cation (SAC) resin.

A second molecule of sodium chloride is clearly needed to free the hardness (calcium) ion and so allow it to start the diffusion process towards the outside of the beads.

The general direction of the regenerant is towards the centre of the beads as the diffusion of the regenerant proceeds from the solution surrounding the beads. Any hardness ion has to move against the regenerant current to leave a particular bead. Once the regenerant has completed its diffusion path to the centre of each bead, then the outward diffusion of the regenerated hardness can presumably proceed more rapidly.

As the regeneration draws to a close, the regenerant is followed by the displacement rinse. Dilution of the regenerant by the displacement water will cause selec-

tivity reversal, thus any hardness ion still situated inside the beads, and travelling towards the outside, will promptly displace two regenerated sodium sites. If the regenerant quantity is cut to a minimum, then the release of the calcium will be slower (see eqn [2]) and the proportion of diluted regenerant to concentrated regenerant will be greater. It follows that the shorter diffusion path offers a more effective regeneration resulting from improved column efficiency.

The use of beads of a narrow size range and core shell beads with a limited diffusion path offers a superior performance; this has already been seen.

Resin Kinetics

Beads of narrow size range can also present a larger surface area of exchange to the water being treated, and therefore the kinetics of exchange may be improved. Larger beads with a shell core formation also provide ease of access to each individual ion exchange site. These features can be important where high flow rates are used. Other significant factors such as resin bed depth, operating temperature, efficient distribution and collection of the water being treated are also important.

Principles of Ion Exchange Applied to Demineralization

The principles applicable to the softening process also apply to demineralization. It is useful to discuss some of these in more detail.

Resin Selectivity

Demineralization requires an ion exchange process of at least two stages. In the first essential stage, the cations in the water to be treated are replaced with hydrogen by passing the water through strong acid cation (SAC) resin in the hydrogen form. When the resin becomes exhausted to the extent that the water is not treated to the required quality, it must be regenerated with acid.

The first stage of the demineralization process may be improved to combine the use of both a SAC resin and a weak acid cation (WAC) resin. The latter is positioned upstream. This is one of the many ways in which the efficiency of this regeneration process can be varied. Returning to the properties of SAC resins, the process is unlike softening in that there are no advantages from changes in ionic concentration when regenerating sodium. The selectivity for sodium, as compared with hydrogen, may be simplified by the following equation.

$$K_H^{Na} = ([Na_R]/[H_R]) \times ([H_S]/[Na_S]) \quad [4]$$

where H is the hydrogen ion; all other symbols as for eqn [1].

It has been reported that K_H^{Na} varies according to the cross-linking of the SAC resin.

Counterflow Regeneration

The advantages to be obtained in water quality from operation in the counterflow mode are, perhaps, even more important than for softening. The difference between the selectivity of sodium and hydrogen is very small (in fact the coefficient lies between 1 and 2). Hence any residual sodium located near the outlet of the bed is easily displaced. Low sodium leakage is clearly an essential parameter where high water purity is required. It follows that either the whole resin bed must be highly regenerated, or the resin bed has to be operated in the counterflow mode. This ensures that the treated water at the bed outlet is in contact with highly regenerated resin containing only minute traces of sodium.

Mixed Bed

The use of a mixture of SAC resins and strong base anion (SBA) resins, regenerated separately before mixing, has generally been considered the best way to achieve treated water of the highest purity. The passage of water alternately via cation and anion resins affords the more or less continuous neutralization of acids and bases produced by contact with the previous bead of opposite charge. The disadvantage is that the component resins have to be separated before regeneration. Incomplete separation will cause the offending beads to be regenerated with the wrong regenerant, resulting in a significant deterioration in treated water quality. Techniques of rinse recycle and efficient counterflow regeneration are now producing water qualities close to that of mixed bed polishing.

Effects of Sodium Leakage

One further problem occurs if the sodium leakage is high. The treated water from the cation resin outlet (decationized water) passes through the anion resin, regenerated to the hydroxide form. In general, this is a very efficient reaction, because the process is one of neutralization of acids, so the exchange reaction is essentially non-reversible, and the only by-product of the neutralization reaction is water. However, any sodium leakage from the cation resin must be accompanied by an anion to preserve electroneutrality. At the start of the cycle, when the anion resin is freshly regenerated, the anion that accompanies sodium will usually be hydroxide. This is not particularly desirable, but is easily removed by the following mixed bed resins. However, as the resin bed exhausts, the

least selective anion, in exhaustion, will accompany the sodium. This anion is usually silica. Silica can cause deposits in superheaters, boilers, turbines and condensers, so accelerating corrosion. Thus it is clear that sodium leakage carries a two-fold danger.

Anion Leakage

The very high selectivity of the anions of mineral acids for ion exchange resins usually prevents high mineral anion leakage, even though regeneration to remove all of these is rarely complete. As with softening, the efficiency of regeneration is crucial if good capacity and low leakage are required. The use of narrow size range resins can shorten the diffusion path in the regeneration process.

Regeneration Efficiency

The regeneration efficiency of cation resins has already been discussed. In the demineralization process, the regeneration efficiency of anion resins is of even more importance.

- During the actual water treatment process, the removal of anions is essentially an acid-base neutralization. Hence it is driven rapidly more or less to completion. However, the regeneration stage involves the exchange of the loaded ions for the hydroxide ion. Hence this stage is a true ion exchange process where the ions being removed are in competition with the ion being fixed on the resin. It follows that the extent of regeneration is the limiting step, dictating the operating capacity of the resin. In fact, when operating SBA resins at recommended flow rates the operation capacity is normally only 5–10% below the available regenerated capacity. In other words, the chromatographic profile is extremely sharp.
- Type I SBA resins do not regenerate easily. In fact the selectivity coefficient K_{OH}^{Cl} is approximately 15–20 for gel Type I SBA resins, and even higher for equivalent macroporous types.
- Type II and acrylic SBA resins are more easily regenerated, but have the disadvantage that they remove silica less efficiently (especially the Type II); both types have poor thermal stability.
- Recently strong base resin types have been compared in their operating performance and related properties. A Type III resin has been developed that is comparable with Type II or acrylic resins in its ease of regeneration, while having thermal stability and silica removal similar to that of a Type I resin.
- Weak base anion (WBA) resins regenerate quite easily, and can be used in conjunction with SBA resins to improve overall regeneration efficiency. However,

Figure 1 Regeneration efficiency of chloride form SBA Type I clear gel anion at 65 g L^{-1} NaOH.

they do not remove silica or carbon dioxide, so the proportion of WBA to SBA must be controlled to balance the needs of the process. Also the fresh regenerant must be used to regenerate the resins in the order $\text{SBA} \rightarrow \text{WBA}$, otherwise the advantage is lost.

The mechanisms for regenerability of anion resins have been discussed in the literature. Briefly, the high selectivity for chloride, sulfate, and nitrate arises from the fact that these ions are less hydrated than is the hydroxide ion. Hence the hydroxide ion prefers to remain in the aqueous phase. As **Figure 1** shows, the lower the moisture retention of the resin, the more difficult is the regeneration process.

These mechanisms also offer good explanations for the variation in thermal stability between resin types. It has been shown that nucleophilic attack on the nitrogen of the active group by the hydroxide ion is responsible for the thermal degradation. It follows that the more hydrated the hydroxide ion, the lower the electron charge density and the lower the rate of degradation. This is confirmed by experimental data. This subject is further complicated by the differences in selectivity of chloride and sulfate ion in the regeneration process.

Principles of Dealkalization

The removal of alkalinity is a less common process than softening or demineralization, hence it will only be dealt with briefly. It has long been recognized that hardness associated with bicarbonates (termed temporary hardness) is more of a problem than that associated with mineral acids (permanent hardness). When water is heated the bicarbonate decomposes to carbon dioxide and insoluble calcium carbonate. This forms the scale that is found in the equipment used to heat or transport water. The removal of scale may be achieved by using a weak acid cation resin regenerated to the hydrogen form.

The reaction:

proceeds quite easily, while the reaction

does not, because the ionized acid produced inhibits further reaction.

The WAC resin is easily regenerated with a stoichiometric amount of acid. This makes the process chemically efficient but it is kinetically slow. It also has the advantage that the total dissolved solids are reduced by the removal of the hardness. The volatile carbon dioxide can be removed by deaeration. The main disadvantage is that acid is needed for regeneration.

An alternative process uses a SBA resin in the chloride form. Here the bicarbonate is exchanged for chloride directly. Thus the offending temporary hardness is exchanged for permanent hardness. There is no reduction in total dissolved solids and the operating capacity is lower, but the advantage is that the SBA resin may be regenerated with common salt.

Principles of Nitrate Removal

The World Health Organization (WHO) limit for potable water is 50 ppm of nitrate. Many water sources have higher levels, partly because of the use of nitrate-based fertilizers to boost crop yields. Although this practice has been curtailed in recent years, the problem will remain for many years to come. Ion exchange resins, regenerated with sodium chloride, selectively remove nitrate in preference to bicarbonate, but not in preference to sulfate. This means that the sulfate in the water is also needlessly removed. The exchange of both nitrate and sulfate can result in the chloride level increasing above WHO limits. Where sulfate levels in the water are significant, the use of a specially developed nitrate-selective (over sulfate) resin can give increased capacity and better overall water quality.

Physical Stability of Ion Exchange Resins

Ion exchange resins have to be physically strong to last for the expected life span of 4–6 years, depending upon the resin type, temperature of operation and regeneration, ability to resist irreversible fouling from trace contaminants in the water to be treated, and adherence to the recommended operating conditions.

This means that they have to be mechanically strong and also able to withstand rapid changes in swelling/shrinking arising from changes in ionic form and changes in ionic concentration. It is most important that the ion exchange plant is designed to accommodate the anticipated changes in bed depth, and resins should be free to adjust to the volume changes occurring naturally through the process. Tests have been developed to evaluate osmotic shock resistance; these are mentioned in other articles.

The elimination of the larger beads in the resin bed will reduce the chances of breakdown resulting from osmotic shock, because the build-up of differential stress with changes in ionic concentration is less in smaller beads. Up to now partially activated beads, which have the advantages of a smaller diffusion path described above, have not been physically stable because of the stresses developing between the swelling and shrinking of the activated part of the resin, compared with the properties of the inert core. There are indications that this difficulty is now being overcome.

Plant Design

Water analyses vary considerably, depending on the source of the water supply and the geographical area. Thus it has been impossible over the years to standardize on one type of plant or on which are the most suitable resins. **Table 2** gives an example of the water analysis information needed to design a treatment plant. Changes in total concentration of dissolved salts, the proportion of sodium and silica (as already discussed), the temperature of the water, the ratio of alkalinity to total anions, and the proportion of sulfates, chlorides and nitrates, all have an influence on the operating capacity and treated water quality.

The presence of iron can severely affect the performance of softeners. Iron can slowly accumulate and cause irreversible fouling. It also acts as a catalyst, promoting oxidation of resins that causes an increase in moisture retention and swelling of the resin. This in turn can cause stress within the resin bed, not only on the resin itself, but also on the internal collectors and distributors. The performance of demineralizers can also be affected, especially if only sulfuric acid is available for resin regeneration and resin cleaning.

Natural organic matter can vary both in quantity and quality from area to area, hence the choice of resins and preferred cycle times, the quantity of sodium hydroxide used for regeneration and its temperature as well as cleaning regimes, can vary from region to region.

Basic Principles

Developments in ion exchange resins since the 1940s have been accompanied by developments in engineering equipment and processes, from the invention of styrene-divinyl benzene resins to advances in techniques for TOC removal. The latter is now of utmost importance for the production of ultrapure water.

The basic principles of sizing an ion exchange vessel are quite simple. Let us suppose that it is necessary to treat $F \text{ m}^3$ of water per hour, and it is required to remove $C \text{ eq m}^{-3}$. Then the load per hour is $FC \text{ mol}$, and FCb is the total load presented for an exhaustion cycle of $b \text{ h}$. It is therefore possible to calculate the volume of resin needed, provided the operating capacity ($O \text{ eq m}^{-3}$) for the particular resin is known for the specified operating conditions. If we have $V \text{ m}^3$ of resin, then for the resin plant to treat the

Table 2 Typical water analysis information

TC, total cation concentration; TA, total anion concentration. Note that TC should equal TA. In general if there is a difference the analysis is probably incorrect. If the pH is not neutral, the hydrogen and hydroxide ions should be included in the balance.

water efficiently, the following equation must be satisfied.

$$FCh = OV$$

where h is the time in hours between successive regenerations.

Many factors can affect the operating capacity in a particular situation. This must always be lower than the total volume capacity of the resin. The most important of these factors are the regeneration level and the particular analysis of the water being treated. In certain cases other factors such as flow rate or cycle time, operating and regenerant temperature, treated water quality and cycle end point, and resin bed depth may also need to be taken into account. Furthermore, the plant itself will need to treat some extra water in order to operate successfully. This extra load needs to be allowed for in the design. The more concentrated the feed water the more extra load is placed on the resin beds. Indeed, the water may contain such a high level of dissolved salts that treatment may not be economic. In such cases RO often provides a satisfactory alternative, or as a pretreatment. When all these factors are carefully considered, the optimization of the plant becomes quite complicated, especially when taking into account the various process options and the possible choices of resin types and their various combinations. Such an exercise requires a vast experience of water treatment. To help design engineers and water treatment plant operators to make suitable design plans, computer programs

are now available. In certain cases they are suitable both for new plant and to revamp or modify existing plant. They may also be used to check the current performance of a particular ion exchange line in operation, and to evaluate possible changes in operating parameters. These programs or computer printouts can be obtained from various resin manufacturers and from original engineering manufacturers to help experts in these calculations. They can also serve as useful training for those engineers learning their trade, and for water treatment chemists who need to understand the operations of a particular plant in which they have an interest.

Table 3 gives an example of data provided by a plant design computer program on the design requirements for a specified flow rate and treated water quality. Table 4 gives an example of the engineering data provided by a computer program. Its use can save many hours in calculation time and allow exploration of the many options available before making a final choice.

Choice of Resins

The optimization of any given process requires considerable skill on the part of the design engineer. It is important to understand the strengths and weaknesses of each resin type so that the correct type and particle size are chosen. The design program is extremely useful to balance and match the conditions of regeneration to produce the correct quality and quantity of treated water. The combined experience of the customer and the engineer, together with the expertise and support of resin specialists, is generally regarded as the best approach to determining the optimized conditions of operation and choice of the correct equipment.

Resin Life

Provided that the design has been optimized, in all but the most difficult cases the resin life should be in the range of 4–6 years, depending on the type of resin. In fact SAC resins have been known to last very much longer, provided they are used at the optimum temperature and are kept free of contaminants and potential oxidizing agents. There must also be the provision that regenerate quantities, concentrations and flow rates are designed to avoid stress on the resins. In many cases regular checks on the state of resins can be beneficial. This will prevent build-up of chemical contaminants and highlight any maloperation before real damage is done.

Introduction

Anion exchange resins consist of a polymeric matrix to which different functional groups are attached. Most weakly basic anion exchangers contain tertiary amino groups; in a few cases primary and secondary groups are also encountered. In many cases weakly basic anion exchangers are not monofunctional but possess a variety of amino groups. Strongly basic resins contain quaternary ammonium groups. Standard commercially available exchangers contain either $-N^+(CH_3)_3$ groups (type 1 resins) or $-N^+(CH_3)_2C_2H_4OH$ groups (type 2 resins). Both weakly and strongly basic exchange resins are available in gel-type or macroporous modifications.

Properties and fields of application mainly depend on the dissociation properties of the functional groups in which dissociation plays the most important role. By means of the mass action law, dissociation constants of the protonated amino and ammonium groups can be estimated. The respective numerical values are in the range of $pK_a > 13$ for strongly basic resins and 5–8 for weakly basic resins. Therefore, strongly basic resins are protonated over the entire pH range but weakly basic exchangers are protonated at pH values below 5–8, depending on the type. As a consequence, strongly basic resins will exchange anions in both acid and alkaline solutions. In addition, these exchangers can adsorb weak acids and even ionize very weakly dissociated acids. Weakly basic resins, however, can operate only in acidic media and are unable to convert neutral salts to the respective hydroxides (e.g. NaCl to NaOH). Furthermore, they cannot normally adsorb weak acids.

The uptake of anions by resins is subject to specific interactions between counterions and co-ions and the distribution of exchangeable ions depends on the properties of both the exchanger and the ions. Consequently, a favoured sorption of certain types of anions occurs. The sequence of affinities is given either qualitatively by the selectivity series or quantitatively by, for example, separation factors. For weakly basic anion exchangers the sequence of most common anions in fresh water is:

actively by, for example, separation factors. For weakly basic anion exchangers the sequence of most common anions in fresh water is:

Due to the dissociation properties of the functional groups, hydroxyl ions are strongly preferred. This is important for the conversion of these resins to the hydroxyl (or free base) form in the regeneration step, in which only slightly more than the stoichiometric amount of OH^- bearing solutions is required.

For strongly basic anion exchangers the selectivity series is:

For these resins hydroxyl ions are the least preferred among the standard anions. Conversion of the resins to the hydroxyl form therefore requires comparatively large excess amounts of sodium hydroxide.

For elimination of nitrate anions from drinking water the preferred sorption of sulfate ions causes considerable disadvantages. Extensive research during the 1980s has shown that this drawback can be overcome by introducing functional groups which are more hydrophobic and bulkier. By these means, the ability to adsorb sulfate ions is considerably decreased. The so-called nitrate-selective resins which are now commercially available contain triethyl instead of trimethyl groups and, therefore, exhibit a reversed preference for nitrate and sulfate ions.

The rate of exchange depends mainly on the internal interdiffusion of exchanging ions. On the completely ionized strong base resins this diffusion is rather quick and the overall rate of exchange mainly depends on the particle size distribution. With weakly basic exchangers, however, the poor dissociation and further specific interactions between functional sites and diffusing ions considerably slow the rate of exchange. For these resins, both the uptake of acids and conversion to the free base form by means of sodium hydroxide strongly depend on the concentration of the liquid phases.

Strongly basic anion exchangers in the hydroxyl form are subject to considerable degradation of

functional groups at temperatures above 40°C, leading to a loss of strongly basic functionality. Weakly basic exchangers are very stable.

Applications

Water Demineralization

The most important application of anion exchangers in water treatment has been in demineralization processes. Demineralization consists of the subsequent cation exchange for hydrogen ions as the first step and either adsorption of acids by a weakly basic exchanger or real anion exchange for hydroxyl ions on a strongly basic exchanger as the second step. As a result, demineralized water is produced: this may be used for various purposes, such as boiler feed water.

The effluent from the preceding cation exchange step consists of a mixture of strong mineral acids and carbonic acid; this is equivalent to the cations originally dissolved. Furthermore it contains silica and dissolved organic compounds, neither of which are retained by the cation exchangers. If no silica removal is needed, weakly basic anion exchangers in their free base form are used to remove strong mineral acids. This process develops as the uptake of acids:

(Parantheses are used to express the stoichiometry of the exchange; R_3 denotes the matrix of the weakly basic exchanger.) In technical filter columns the uptake of sulfuric and hydrochloric acid results in the development of zones with different predominant loadings: firstly, a sulfate-rich zone close to the inlet; secondly, a chloride zone; and finally, a zone in which the resin is still in the free base form. During the filter run the sulfate and chloride zones become larger and the boundaries between the zones are shifted towards the column outlet. Consequently, chloride ions are the first to appear in the column effluent.

Theoretically, the strong acids should be completely eliminated. In practical installations, however, the leakage of sodium from the strongly acidic cation exchanger cannot be avoided and it is in the range of 2–50 $\mu\text{g L}^{-1}$, depending on the level of regeneration. By this means, the feed solution for the anion exchanger contains some neutral salt which cannot be eliminated. Consequently, an equivalent amount of chloride ions remains in the effluent. Apart from this sodium leakage-caused ‘slip’, the presence of chloride

ions may also be due to the hydrolysis of the hydrochloride form of weak base resins:

Weak acids like carbonic acid are only adsorbed to a small extent and hydrogen carbonate ions are rapidly replaced by anions of strong acids. Carbonic acid or CO_2 is therefore eliminated either by physical degassing or by means of a strongly basic exchanger. Since the capacity of weakly basic resin increases with increasing total ionic concentration (to which carbonic acid contributes), degassing of CO_2 is often placed after the weakly basic exchanger filter.

Regeneration of weakly basic anion exchangers is usually carried out by means of sodium hydroxide, although other chemicals like $\text{Ca}(\text{OH})_2$ or ammonium hydroxide have also been proposed. To avoid the precipitation of calcium sulfate, the regenerant solutions of anion exchangers generally require calcium-free water. Since the strong acids are easily neutralized, regeneration is efficient. The operating capacity depends on the composition of the raw water and the resulting loading of the anion exchanger. If equal amounts of caustic are applied in the regeneration step, the effective capacity decreases by about 10% if the raw water contains exclusively sulfate instead of only chloride ions.

Unlike with weakly basic resins, the removal of acids by a strongly basic resin develops as a neutralization reaction:

(R_4 denotes the matrix of the strong base resin.) Because of the high pH value in the resin phase, strongly basic exchangers can ionize and adsorb ions from carbonic acid and even from silica:

For boiler feed water, for example, the removal of both carbonic acid and silica is of great interest. Usually, most of the carbonic acid is removed by physically degassing. By this means a large part of the capacity of the strongly basic anion exchanger is saved and the resin has to eliminate only the remaining traces of carbonic acid. The removal of silica is far more complicated than shown in eqn [5] above.

Figure 1 Interdependence of sodium and silica leakage.

During the accumulation in the resin phase, silica starts to polymerize. This is favoured by long cycles as well as by high concentrations in the feed water. Regeneration using NaOH may, therefore, become a dissolution rather than a true ion exchange process. Warm solutions (approximately 50°C) are considerably more effective than solutions at ambient temperature. In addition, regeneration may be adversely influenced by the mode of regeneration and the possible displacement of hydrogen carbonate ions. The leakage of silica is closely related to the leakage of sodium in the preceding cation exchanger (**Figure 1**).

Regeneration of strongly basic resins is generally carried out by means of NaOH at concentrations between 1 and 5%. As with weakly basic exchangers, the resulting operating capacity depends on the composition of the feed water, the relative amount of NaOH, temperature and, to a certain extent, the rate of filtration during regeneration. The relative quantity of NaOH required is considerably higher than for weak base resins and lies between 150 and 250% of the stoichiometric amount. For the slightly weaker basic resins of type 2, the operating capacities are higher than for type 1 resins.

There can therefore be savings in chemicals and cost if the anion exchange step is split into two stages. In the first stage a weakly basic resin is applied for the elimination of strong acids. After physical degassing to remove carbon dioxide, the strongly basic exchanger is exclusively used to eliminate the remainder of the carbonic acid and silica. Both resins are regenerated together: the NaOH solution first passes through the strongly basic resin which requires a concentrated regenerant without impurities. The effluent

then passes the weakly basic resin. Due to the strong preference for hydroxyl ions, considerable levels of impurities can be tolerated.

Demineralization of water by subsequent or simultaneous cation/anion exchange has been realized in countless installations for both fresh and waste water treatment. It has become extremely important for boiler feed water and for ultrapure water for the electronics and pharmaceutical industries. Typical conditions to be met are conductivities below 0.2 $\mu\text{S cm}^{-1}$ and silica concentrations $< 5 \text{ mg L}^{-1}$.

Partial Demineralization of Drinking Water

In Europe numerous water supplies distribute drinking water with elevated total hardness caused by the presence of sulfate and calcium ions. Treatment of such water, therefore, requires the elimination of sulfate ions parallel to diminishing hardness. In such applications complete demineralization is not required. Consequently, considerable leakage of the ion exchangers can be tolerated. The condition of simultaneously diminishing the concentrations of alkaline earth and sulfate ions is met by the carbon dioxide regenerated ion exchange (CARIX) process. This process uses a mixed bed consisting of a weakly acidic resin in the free acid form and a strongly basic resin in the hydrogen carbonate form. In contact with calcium- and sulfate-bearing raw water, both kinds of ions are replaced by carbonic acid:

The advantage of this process is its reversibility: for regeneration, carbon dioxide is dissolved in untreated raw water under a pressure of typically 0.4–0.5 MPa. The carbonic acid solution is pumped across the mixed bed and simultaneously regenerates both resins. Although carbon dioxide is applied in large excess, this does not contribute to the salt content of the waste water which exclusively contains the ions removed during the service cycle. Carbonic acid is a weakly effective regenerant for both resins and generates an effective capacity of $\approx 50\%$ of the total capacity on the cation exchanger and only 20% on the anion exchanger. As a consequence, complete demineralization is not possible and considerable leakage is observed. The possible throughput between two regenerations is small. Within certain limits the

Figure 2 Concentration histories of chloride, nitrate and sulfate in the Carix process. Feed alkalinity (HCO_3^-): 6.5 mmol L^{-1} . Circles, Cl^- ; triangles, NO_3^- ; diamonds, SO_4^{2-} ; squares, HCO_3^- .

CARIX process can be adapted to the objective of treatment by adjusting the volume ratio $V_{\text{anion}} : V_{\text{cation}}$ of the two resins in the range of 3 : 1 to 1 : 3. With respect to both the removal of sulfate and regeneration by means of carbonic acid, type 2 and acrylic anion exchangers show the best results.

So far, the process has been realized in three full-scale plants in water works in Germany. Each of these plants consists of one or two sets of three filters which operate in a merry-go-round mode. The total throughput for each filter between two regenerations is 35–50 bed volumes. After half of the total throughput, a second filter starts its service cycle. After the full throughput, the filter is regenerated and waits for the next service cycle while the third one is started. The product water is the mixed effluent of the two operating filters. Typically, about 10% of the raw water is needed for regeneration. From the waste water, 90% of the unspent carbon dioxide is recovered. Thus, the consumption of CO_2 amounts to $0.4\text{--}0.45 \text{ kg m}^{-3}$.

Figure 2 shows a typical breakthrough history for standard anions. Average product water concentrations are listed in Table 1.

Nitrate Removal

For many drinking water supplies the presence of nitrate in ground and surface water at elevated concentrations has become a serious problem because of its health effects. As the simplest possibility, nitrate can be eliminated from water by means of strong base anion exchangers in the chloride form:

Using conventional strong-base anion exchangers, the main difficulty of this method arises from the

Table 1 Partial demineralization by means of the CARIX process

Parameter	Raw water	Product water
Total hardness	5.4 mmol L^{-1}	2.3 mmol L^{-1}
Hydrogen carbonate	6.6 mmol L^{-1}	3.4 mmol L^{-1}
Sulfate	1.6 mmol L^{-1}	0.35 mmol L^{-1}
Nitrate	0.6 mmol L^{-1}	0.45 mmol L^{-1}
Chloride	1.5 mmol L^{-1}	1.3 mmol L^{-1}
Conductivity	$930 \mu\text{S cm}^{-1}$	$470 \mu\text{S cm}^{-1}$
pH Value	7.30	7.80

preferred uptake of sulfate ions. Consequently, the nitrate uptake capacity strongly depends on the sulfate/nitrate concentration ratio in the raw water. As an example, for a type 2 resin the nitrate uptake capacity decreases by 60% if the sulfate concentration in the feed increases from 50 to 220 mg L⁻¹.

During the uptake of sulfate, nitrate and hydrogen carbonate by a chloride-loaded conventional anion exchanger, loading zones develop in the filter column: a sulfate-rich zone, a nitrate-rich section and a mixed chloride/hydrogen carbonate zone followed by the resin in its original chloride form.

Due to the development of the zones and the displacement of less preferred anions, continuous change occurs in the effluent composition. When the hydrogen carbonate-rich zone has reached the outlet there is still removal of nitrate species, but an increase in the concentration of hydrogen carbonate and a corresponding increase in the pH in the effluent occur. The column run has to be stopped when the nitrate-rich zone reaches the filter outlet.

Regeneration is carried out using brine solutions of 2–10% NaCl:

The total quantity of NaCl used depends on the tolerable nitrate leakage in the service cycle. To achieve effluent concentrations ≤ 2 mg L⁻¹, the required amount is ≥ 200 g L⁻¹ resin. With smaller quantities the leakage becomes larger.

The operating capacity of conventional anion exchangers depends on both the nitrate and sulfate concentrations of the feed water. Figure 3 shows the respective interdependence for a commercially available type 2 resin.

The objective of treatment normally does not consist of the complete elimination of nitrate but only of its reduction below the maximum permitted concentration. A tolerable nitrate concentration in the product water can therefore be achieved by two different methods: the first uses an exchanger which has been regenerated with a large amount of NaCl. Since the leakage of the column is small, only part of the water has to be treated and can be blended with a by-pass of untreated water.

This kind of nitrate removal process was first realized in 1975 in Long Island in a pseudo-continuous installation. This plant consisted of a closed-loop tube including sections for back-washing, regeneration

Figure 3 Operating capacity of a type 2 strongly basic anion exchanger depending on the concentrations of nitrate and sulfate in the raw water. Continuous line, 0.36 mmol L⁻¹; dashed line, 0.72 mmol L⁻¹; dotted and dashed line, 2.1 mmol L⁻¹. Resin: Lewatit M600.

Table 2 Data of operation of Ecodenit plant

Parameter	Feed water concentration (mg L ⁻¹)	Product water concentration (mg L ⁻¹)	Waste water concentration (g L ⁻¹)
Nitrate	70	25	25
Sulfate	50	10	10
Hydrogen carbonate	65	55	55
Chloride	50	120	120

and rinsing of the exhausted resin. After exhaustion the resin material in the contacting section is pulsed into the back-wash part, whereas regenerated and rinsed resin material enters the contacting section. The plant was designed for a maximum throughput of 277 m³ h⁻¹. The nitrate concentration was diminished from 100 to 43 mg L⁻¹ as the tolerable maximum.

In the second possibility the amount of NaCl required during regeneration is smaller. As a consequence, the regeneration is less efficient and the nitrate leakage becomes larger. Thus, all the water has to be treated. This principle is shown in the Ecodenit process developed in France. This process operates with NaCl quantities of ≤ 100 g L⁻¹ of resin and uses co-flow regeneration. The first full-scale plant for the treatment of 160 m³ h⁻¹ is in service in northern France. This plant consists of three filters operating in a merry-go-round mode. Each filter contains 8 m³ of a strongly basic resin. Results of the operation of the full-scale plant are summarized in Table 2.

Both principles are combined in a third modification. Such a plant went into service in 1983 in California. The plant was to treat 115 m³ h⁻¹ blended with 45 m³ h⁻¹ raw water. It consists of three columns which are also operated in a merry-go-round mode. For each filter the throughput between two regenerations amounts to 250 bed volumes. The nitrate concentration is decreased from 71 to 11.5 mg L⁻¹ in the mixed effluent of the service filters and to 27–36.5 mg L⁻¹ in the blended product water. Since 1983, numerous nitrate elimination plants have come into service: most apply nitrate-selective exchangers.

Chromate Removal

Chromic acid and chromates are widely used in many applications. Anion exchange offers an ideal opportunity for the removal and recovery of chromates. Both strongly and weakly base resins can be applied.

In aqueous solutions chromate ions exist in different ionic forms. The speciation mainly depends on the pH value. In the acidic region ($1 < \text{pH} < 6.5$) and for

dilute solutions, HCrO₄⁻ is the predominant species. Above pH 6.5 mostly CrO₄²⁻ is found. With respect to ion exchange processes it is important that dimerization occurs at elevated concentrations:

The respective pH conditions may exist in the anion exchanger phase. Therefore, the resins can be considered to be at least partly loaded with Cr₂O₇²⁻ species.

Chromate species are strongly preferred over chloride and sulfate ions under normal conditions. However, at acidic pH this preference vanishes for both weakly and strongly basic anion exchangers when chromate is the trace component. Consequently, fixed-bed experiments using standard acidic chromate-bearing waste waters exhibit a gradual increase in the effluent concentration. An increase in the concentration of competing sulfate ions yields only a negligible decrease in chromate capacity. In contrast to this, an increase in the chloride concentration leads to a considerable decrease in chromate capacity for a given liquid-phase concentration. For weakly basic resins the chromate capacity decreases with increasing pH because of the deprotonation of the functional groups. Below pH 5 the capacity is constant and depends only on the background composition of the solution.

Using strongly basic exchangers chromate can be removed by the following exchange processes:

Weak base anion exchangers are applied, for example in the sulfate form:

Acidification of the feed solution leads to the formation of hydrogen dichromate species, which doubles the capacity of the resins, e.g.:

Figure 4 Elimination of Cr(VI) from cooling tower blowdown. Effluent concentration histories of loading (circles) and polishing (squares) columns. Feed water composition: Cl^- (500 mg L^{-1}), SO_4^{2-} (200 mg L^{-1}), Cr(VI) (10 mg L^{-1}), HCO_3^- (100 mg L^{-1}), $\text{Ca}^{2+} + \text{Mg}^{2+}$ (5.5 mmol L^{-1}), Na^+ (250 mg L^{-1}). Resin: Amberlite IRA 94.

After exhaustion, treatment with NaOH will convert hydrogen dichromates to chromates and, subsequently, yield half of the chromate loading on elution. Removal of the remainder of the chromate from the strongly basic exchanger requires concentrated sodium sulfate solutions:

In contrast to strongly basic exchangers, weakly basic ones can be completely regenerated by means of NaOH. However, before the following service cycle, the resins have to be reconverted to the sulfuric acid form:

Chromate species elimination from cooling tower blowdown has been achieved by application of a styrene weakly basic resin in a merry-go-round system with three columns. In the plant, column 1 serves as the crude loading column which eliminates most of the chromate. The relatively low effluent concentrations are further decreased by the second (polisher) column. The third column is regenerated/conditioned or waits for service. When the maximum tolerable effluent concentration of the polisher column is exceeded, the sequence is switched

so that the polisher column now acts as the loading column and the freshly regenerated filter is applied for polishing. The previous loading column is regenerated and conditioned. A typical example is given in Figure 4.

Removal of Organic Substances

Natural organic substances normally have an anionic nature at pH values above neutral. Apart from their elimination in a suitable pretreatment step, they can be adsorbed by both weakly and strongly basic anion exchangers. Uptake of organic substances is due to both ionic and van der Waals forces. They may present a problem for anion exchangers because of a possibly irreversible adsorption by styrene-based gel-type resins.

Both types of exchangers, therefore, can act as scavengers for the removal of organic compounds prior to further ion exchange steps. In general, strongly basic exchangers exhibit a better elimination of humic substances. For demineralization of industrial water they are applied in the chloride form as scavenger units at the head of the deionization train. The basic problems associated with the application of anion exchangers as scavengers in demineralization plants are the additional exchanger unit and the exchange of the organics and hydrogen carbonate ions for chloride. Thus, the effluent composition may be less favourable for the application of weakly acidic exchange resins.

Depending on the total concentration of organic matter in the feed water and to the desired level in the effluent, different resin types are recommended. The combined application of weakly and strongly basic

resins has been successfully applied in the Stratabed® concept, in which two layers of the respective resins, both of the polystyrene type, are used. The application of this concept requires the use of exchange resins with a particle size distribution which allows the maintenance of the stratified bed in each column. Since regeneration is carried out using warm NaOH solution, precipitation of silica is avoided. Favourable conditions are met: waters of poor alkalinity and chloride and sulfate are the major part of the anions present. Acrylic anion exchangers allow a reversible uptake of humic acids. Although the capacity of acrylic resins for organics is poorer, they are highly effective. They can be used in all applications except in condensate polishing with extremely high flow rates. Under these conditions the elastic properties of these resins exclude their use.

At low levels of organic matter in the feed water the application of macroporous weakly basic resins in their free base form in the de-ionization train allows an efficient removal. Furthermore, these resins are less susceptible to irreversible fouling.

In drinking water treatment, macroporous styrene-based strong base resins were employed in Hanover in Germany as a single treatment step for the removal of organic matter from ground water. Dissolved organic carbon was to be reduced from 6.5 to about 3 mg L⁻¹. After 5000 bed volumes, the resin was regenerated by means of an alkaline NaCl solution which could be reused seven times. The plant was shut down in 1995.

Apart from the elimination of natural organic matter, anion exchangers may also be applied to the removal of organics from different types of waste water. Weakly basic resins have been used for the removal of phenol. Sorption is carried out at rather low flow rates of 2–8 BV h⁻¹. NaOH or organic solvents are used for regeneration. Macroporous weakly basic resins in the sulfuric acid form are applied for decolorization of kraft bleach liquors. After exhaustion they are regenerated using NaOH and conditioned by means of sulfuric acid.

Introduction

Grain fermentation yields a water-based liquid mixture commonly referred to as distiller's beer. This beer will typically contain between 5 and 9% by weight ethyl alcohol, 6–8% by weight residual grain solids, and a very small quantity of other compounds known as fusel oils. These fusel oils, also known as congeners, are primarily higher alcohols that are soluble in ethyl alcohol but only partially soluble in water. The congeners contribute to the taste and aroma of whisky and are not typically removed in a single-column distillation.

All separation technologies exploit some difference between items in a mixture or solution in order to cause them to separate. These differences may be physical, chemical or electrical in nature. In particular, distillation takes advantage of the difference in boiling points to separate soluble liquids from one another. Not all liquid solutions may be economically separable by distillation for a variety of reasons. For example, one or more of the liquid components may not appreciably volatilize, or the change in the concentrations of the components between the gas phase and the liquid phase may be so small that the process becomes impractical. It may even happen that there is no change in the composition whatsoever.

In general, during distillation of completely miscible liquids, the component with the higher boiling point moves toward the bottom of the still while the component with the lower boiling point moves toward the top. In whisky production, water boils at a higher temperature while ethyl alcohol boils at a lower temperature. As a result, distillation has an added benefit as the separation technique of choice, because the grain residue is naturally carried to the bottom of the still along with the water. If the still is properly designed, the concentration of alcohol in the still bottoms should be negligible and the discharge from the bottom of the still will contain all of the unwanted grain residues and the excess water.

Vapour–Liquid Equilibrium

In order to understand what happens during the distillation process, we need to address the topic of vapour–liquid equilibrium. For the purpose of this discussion, we will consider the case of distilling a mixture of water and ethyl alcohol at a constant pressure of 1 atm. **Figure 1** shows the vapour–liquid equilibrium curves for this mixture. It should be noted that the concept of a single boiling point is invalid for this type of solution. The lower line is referred to as the bubble point line. At a given concentration of ethyl alcohol in a liquid mixture of ethanol and water, the bubble point line indicates the temperature at which the first bubble of vapour forms as the solution is heated. The upper line is called the dew point line. At a given concentration of ethanol in a vapour mixture of ethanol and water, the dew point line indicates the temperature at which the first drop of condensate is formed as the mixture is cooled.

In order to explain the distillation process, a rather simplistic approach is employed by assuming an absolutely ideal system with no inefficiencies. For actual distillation system design, a much more thorough analysis would need to be done. For illustrative purposes, let us assume we have a liquid solution consisting of 40% by weight ethanol and 60% by weight water in a pot at 82°C. **Figure 2** shows the vapour–liquid equilibrium of this solution, which is currently at point A. Let us further assume that we will add heat to this pot in an effort to bring the temperature up to 99°C, as represented by point B (**Figure 3**). The solution will heat up until the

Figure 1 Vapour–liquid equilibrium: ethanol–water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

Figure 2 Vapour-liquid equilibrium: ethanol-water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

Figure 4 Vapour-liquid equilibrium: ethanol-water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

temperature reaches about 83°C where the heating line intersects the bubble point line at point M. At this point, the first bubble of vapour forms, but because the ethanol vaporizes more easily than the water at this point, the vapour phase is enriched in ethanol. The concentration of ethanol in this first bubble of vapour is found at point N, about 75% ethanol by weight (Figure 4). As the mixture continues to heat up, eventually point P is reached at about 87°C. At this point, the mixture is boiling. The liquid still in the pot has a concentration of about 17%, as indicated by point O, while the total vapour concentration is represented by point R at about 64% ethanol (Figure 5). The solution can continue to be heated until the heating line intersects with the dew point line at point T. At this point there is only one drop of liquid left in the pot and its concentration is found at point S to be about 2% ethanol by weight. If all of the vapour from this experiment was collected, its concentration would be found at point T – approximately 40% by weight ethanol – right back where we

started from, only hotter. The vapour could then be superheated to 99°C at point B, but no further changes in ethanol concentration would occur.

It should be noted that, during the distillation process, once the bubble line is reached, the concentration of ethanol in the liquid phase moves along the bubble point line from left to right, constantly decreasing until the supply of liquid is exhausted. Similarly, the concentration of ethanol in the vapour phase also decreases, along the dew point line, as the liquid in the pot is exhausted. As a result, if we were going to distill ethanol from water in a batch process with a lower limit of acceptable proof, we would have to stop the process before all the ethanol could be recovered. Ideally, we would like to be able to recover all of the ethanol from the solution at some specified constant proof. If point N is the target, we could devise a process where we continually replenish the liquid in the pot at 40% ethanol and a rate equal to the rate that product is taken off by condensation.

Figure 3 Vapour-liquid equilibrium: ethanol-water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

Figure 5 Vapour-liquid equilibrium: ethanol-water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

Figure 6 Vapour-liquid equilibrium: ethanol-water, 760 mmHg. Continuous line, bubble point line; dashed line, dew point line.

If a concentration greater than that represented by point N is desired, a single pot cannot accomplish the task (**Figure 6**). Suppose, however, that we set up an apparatus whereby we constantly feed the first pot as described earlier, but now we condense the product vapour and put it in another pot where it can be distilled a second time. The concentration of the vapour from the second pot is represented by point X, about 82% by weight ethanol. It can be seen that adding more pots to this scheme would result in higher and higher concentrations of ethanol in the product. There is, however, a limit to this approach. As the bubble point and dew point lines get closer together, the increase in ethanol concentration per added pot decreases. Eventually, these two lines touch. The point at which these lines touch is called an azeotrope. Azeotrope is a Greek word meaning 'to boil together'. Literally, at this point additional separation by conventional two-phase distillation is impossible because the liquid- and vapour-phase concentrations are identical. In fact, even getting close to the azeotrope requires more advanced distillation practices than those commonly used in whisky production.

By analogy, it can be seen that the problem of recovering the residual ethanol from the still bottoms can also be accomplished through the use of additional distillation stages. In practice, however, the distillation column is a more efficient method of accomplishing these distillation tasks than multiple pot stills. Single malt Scotch whisky makes use of multiple pot stills in the production of their final distillate in a manner similar to that described above.

The Continuous Beer Still

The first distillation element in a multicomponent whisky distillation system is commonly referred to as

Figure 7 Cut-away of typical distillation column.

the beer still. The beer still consists of a cylindrical shell and number of evenly spaced trays connected by pipes called downcomers. **Figure 7** shows a cut-away view of the inside of a typical beer still. The liquid in the still moves across the trays and down the downcomers. The vapour in the still moves up the column through holes in the tray and through the liquid. The pressure of the vapour under each tray must be great enough to allow the vapour to pass through the holes and through the liquid to the next level up the tray without allowing the liquid to drip through the holes (**Figure 8**). Each time the vapour passes through the liquid, the vapour gains ethanol concentration while the liquid loses ethanol concentration. One tray is roughly equal to one distillation in a pot similar to that discussed earlier. Technically, the vapour condenses in the liquid of the tray above it, and gives off its heat of vaporization. This heat of vaporization in turn revaporizes a corresponding volume of vapour which is richer in ethanol.

The still is conceptually divided into two sections, the stripping section and the rectifying section. The stripping section is the part of the still that is on and below the feed-tray level. This section is referred to as

Figure 8 Typical plate flow detail.

the stripping section, because here the residual alcohol is essentially stripped from the feed stream so that the still bottoms have a negligible presence of ethanol. The still must be designed not only to produce a spirit of the desired proof, but also to limit base losses. Typically, the stripping section has about 16–20 plates. The plates in this section must be designed to minimize the likelihood of fouling due to the grain residue being present here. Almost exclusively, sieve trays are used for this purpose because they have larger, less complex vapour openings and wider tolerances to help prevent plugging with grain particles. The space between the trays must also be sufficiently wide to prevent foam and other entrained liquid on one tray from influencing the tray above it.

It is possible for grain particles in the feed to be entrained in and carried upwards by the vapour passing through the feed tray. This can happen on any tray in the stripping section, but it is most critical on the feed tray. Various approaches have been utilized to minimize this problem; almost all are mechanical alterations to the still itself. The most common de-entrainment device is the use of one additional sieve tray immediately above the feed tray.

The rectifying section of the still is the part that is above the feed tray. In this section, the alcohol is concentrated to the desired product proof. Typically, the rectifying section has between two and five plates. The plates in this section are designed to cause more efficient commingling of the vapour with the liquid as the vapour passes through the plate. Since solids are no longer an issue, the contacting mechanisms can be

more intricate and tolerances closer in this section. The plates in this section may also be more closely spaced because foaming and entrainment are much less of a problem here than in the stripping section.

The Beer Heater

As a rule of thumb, the conditions of the feed stream to the still should match, as closely as possible, the conditions on the tray to which the feed is introduced. It has already been noted that the ethanol concentration of the feed stream is generally between 5 and 9% by weight. The concentration can be closely predicted from heat and material balance calculations where no empirical data exist for a given feed stream. It has also been noted that the feed tray is generally near the 18th plate. The feed tray location can also be predicted from detailed will design calculations. The only problem that remains, then, is the feed temperature. When fermentation is complete, the beer temperature is generally about 34°C. The feed tray liquid temperature should be about 93°C. Since the vapour from the still generally has to be cooled and condensed, it provides a convenient source of heat to pre-heat the beer. Usually, the beer feed is passed through a shell and tube-type heat exchanger with large diameter tubes to help alleviate plugging. The vapours from the still are on the shell side of the exchanger.

The condensate from the beer heater is generally returned to the still as reflux. Reflux is the liquid returned to the top of the still. It alters the number of trays required to perform the desired degree of separation as well as the tower cross-sectional area and the heating and cooling loads required for vaporization and condensation. Reflux is generally referred to as a ratio of the liquid returned to the still versus product collected. As the reflux ratio goes up, the number of trays required to perform the separation goes down, but the requisite heating and cooling loads go up. At infinite reflux, the minimum number of trays is achieved, but the maximum heating and cooling loads are required. At minimum reflux, an infinite number of trays is required for the separation, but minimum energy requirements are achieved. An optimum reflux ratio can be calculated and the beer heater can be designed to provide that reflux.

A general rule of thumb for still design would require that the reflux be introduced to the still on the top plate because of its temperature and composition. However, many distillers have made the decision to enter the reflux lower down the column near the beer feed plate for quality reasons. Additionally, the final distillation proof in whisky production is only partly determined by economic considerations. Depending

on the type of whisky being produced, there are generally governmentally prescribed maximum ethanol concentrations which may be permitted during the distillation process. In the case of bourbon, the US Bureau of Alcohol, Tobacco, and Firearms prescribes that the distillate may be taken from the still at no higher than 160 proof (80% ethanol by volume). Of utmost importance, however, are the organoleptic considerations which go into the production parameters for the whisky. Product taken off at a lower proof retains more of the grain character, while product taken off at a higher proof tends to have less of the grain flavour constituents.

The Doubler

Many distillers utilize a doubler in their whisky distillation process. The doubler is basically a pot still, like the one discussed earlier. The doubler acts as one additional distillation stage. It is used in practice for final proof adjustment and for product quality enhancement. There are two fundamentally different ways of operating the doubler. The first is called true double distillation. In true double distillation, the still vapours generally pass through the beer heater first, and then one or more condensers, so that the product is completely condensed back to a liquid form. This liquid is then charged to the doubler where it is heated with steam coils and re-vaporized. The vapour from the doubler is then condensed again and taken off as product.

The doubler can also be operated as a thumper. In this case, the doubler is fitted with a large sparger. The doubler is charged with liquid to a level just above the sparger. The liquid is typically demineralized water or the low proof tails cut from a previous distillation. The vapour from the still first passes through the beer heater then through the sparger in the doubler where it bubbles through the liquid. As the vapour passes through the liquid in the doubler, it flash condenses and gives off its heat of vaporization which, in turn, revaporizes a corresponding volume of vapour which is richer in ethanol. The thumper gets its name from the sound made as the vapour condenses while passing through the liquid. Finally, the ethanol-enriched vapour passes through one or more condensers and is taken off as product.

Reboilers

Most beer stills are heated by direct steam injection from a low pressure steam sparger located in the base of the still. A reboiler is a type of heat exchanger which permits the use of higher pressure steam than a steam sparger will allow. There are several advantages

to using a reboiler. First, it acts as one theoretical plate in the distillation column. Second, it saves on the amount of waste to be disposed of from the still bottoms because it adds no water to the system. However, reboilers are not generally used in whisky production because they have a great tendency to scorch the grain in the bottoms and, hence, degrade the product quality. In other stills with no grain residue, reboilers have been used quite successfully.

Process Control

Control of the continuous beer still is generally accomplished by means of three interrelated control loops. These loops regulate the level of the liquid in the bottom of the still, the flow of steam into the bottom of the still and the flow of the beer feed near the top of the still.

Typically, the liquid level in the bottom of the still is sensed by a level transmitter which, in turn, regulates a control valve on the discharge of a continuously running base level pump. Alternatively, in certain configurations, the base level can be regulated very simply by means of a float valve set at a certain level. This requires that the discharge be capable of gravity flow away from the still bottom. Additionally, newer technology has made it possible to dispense with the control valve on the base level pump. The level transmitter can provide a signal to a frequency inverter which controls the frequency of the electrical current running the pump. This frequency shift will cause the pump to speed up or slow down in relation to the signal from the level transmitter.

In a similar manner, the steam flow to the still is generally held at a constant base pressure or a constant flow rate. Base pressure control is the most common means of steam control. A pressure transmitter in the base of the still above the liquid level provides a control signal to a control valve which, in turn, regulates the flow of low pressure steam into the steam sparger in the bottom of the still. If steam flow control is desired, an orifice plate or vortex flow meter is inserted into the steam line. The flow-sensing device provides the control signal to regulate the control valve. In the past, some distillers have used the still top temperature as a means of regulating the steam flow, while holding the beer feed constant. While this means is effective, it tends to be less reliable due to the relatively large amount of process response lag time.

The beer feed is generally regulated by means of sensing the still top temperature, which is directly related to the proof of the distillate. A temperature transmitter generally provides a control signal to

a process control valve in the beer feed line, which is fed by a constantly running feed pump. More recent technology has made it possible to control the proof more directly by using the temperature-corrected density function of a mass flow meter, which can be correlated to the proof of the discharge from the still. The only downside to the use of a mass flow meter is the process lag time that results from having to measure the proof of the distillate after condensation. Additionally, the control valve can be eliminated from this loop by using a frequency inverter, as described above. Some distillers employ a more sophisticated means of controlling the beer feed to the still by use of a cascaded control loop. Typically, a magnetic flow meter is used to measure the flow of beer to the still and control the operation of the control valve. The still top temperature transmitter provides a signal which is used to manipulate the control settings for this flow control loop.

In addition to the above controls, one or more condensers must also be controlled. Generally, a control valve on the inlet cooling water line is used to control this process. The control signal typically comes from a temperature transmitter which can either be located on the discharge water line or the discharge product line. Due to the relatively quick flow rate of the cooling water with respect to the product flow rate, process control response is generally much better if the temperature transmitter is located on the cooling water discharge line.

Finally, if the product is double-distilled in a true doubler, one additional control loop is required. The steam flow to the steam coils inside the doubler must be regulated. Almost without exception, this loop consists of a steam control valve and a temperature transmitter on the vapour discharge from the doubler. In a manner similar to the still top control,

new technology has made it possible to control the discharge proof more directly using a mass flow meter.

Conclusion

A sign at the Stitzel-Weller distillery in Louisville, Kentucky sums up the traditional view of the impact of science on the beverage alcohol industry:

No Chemist Allowed

Nature and the oldtime know-how of the master distiller get the job done here. Because traditional Kentucky whisky is a natural product, we disdain synthetics, scientist, and their accompanying apparatus. This is a distillery, not a whisky factory.

Pappy Van Winkle

Tradition handed down through the generations is the predominant means of whisky production. There are numerous stories of a distiller who had to replace his still because it had worn out. When the new still was being installed, the distiller would make sure that it was identical to the one it was replacing, right down to the dent in the side of the still, which was generally reapplied by the master distiller himself. As a result, technological change is slow to be adopted in an industry where any change in the process may result in a changed taste. Technology is gaining a foothold in the area of process control, where new and better final control elements, transmitters and control systems are always being applied. This traditional approach has also resulted in an almost complete lack of published literature on the topic of whisky distillation, which at best is viewed by the industry as only part science and part art.

Introduction

From the chemical point of view, wines are aqueous alcoholic solutions containing more than 1000 components that can be present at high concentrations (g L^{-1}), but also at trace levels (ng L^{-1}). Some of

these components determine the organoleptic properties of wines, while others are significant for classifying their origin and/or for checking whether some adulteration has taken place. Concentration levels of these compounds vary according to the variety of vine, the climatic conditions under which the grapes were grown, and the conditions under which vinification and ageing processes have been developed.

The quality of wines is established by sensory analysis, which is clearly correlated to their chemical

composition. To assure and control this quality, some essential parameters and characteristic compounds are determined by physical and chemical analyses, which are established principally by the *Office International de la Vigne et du Vin* (OIV). Other constituents whose determination is included in these methods are those associated with the toxicity of wines or which are allowed to be present to some maximum permissible levels.

Until recently, the techniques used in the analysis of this broad variety of properties and compounds have been based on classical methods (mainly gravimetric, titrimetric and colorimetric), which allow an adequate control of the vinification in the wineries. Although chromatographic techniques are not widely used in the OIV methods, the complexity of wine composition has pointed to the use of chromatography in many oenological laboratories, and the improvement in the analysis of wines is undeniably bound up with the development of chromatography.

Almost all the chemical compounds present in wines can be analysed by chromatography, either by direct injection or by prior derivatization. For volatile, thermally stable compounds, gas chromatography (GC) is the most used technique, while for the analysis of nonvolatile and thermally unstable compounds, high performance liquid chromatography (HPLC) is preferred. These techniques are considered in more detail below.

Gas Chromatography

Gas chromatography has been responsible for the most important advances in the knowledge of the volatile fraction of wines. Although the non-volatile fraction can also be analysed by GC after derivatization of the analytes, HPLC methods are simpler and therefore they are preferred for these compounds.

The main application of GC to wine analysis is the study, characterization and determination of the aroma of wines, which originates from their volatile components. Aroma compounds are usually classified according to their chemical functionality, the most important being esters, alcohols, acids, lactones, carbonyl compounds, volatile phenols and sulfur- and nitrogen-containing volatiles. With the exception of ethanol and glycerol, the concentrations of the individual aroma compounds range from 100 mg L^{-1} to 0.1 ng L^{-1} . The human sensory organs are extremely sensitive to certain aroma substances, which can show sensory thresholds much lower than their concentrations in wine. The analysis of wine aroma must, therefore, be optimized in order to determine all these compounds. To perform this kind of analysis, two

different steps must be considered: sample preparation and gas chromatographic separation.

Sample Preparation

The sample pretreatments are conditioned by the wine matrix and the character and the concentration of the analytes to be determined. Wines can be directly injected, but it is more common to inject the extract obtained after the application of pretreatment techniques.

Direct injection is applied to the analysis of the volatiles whose concentration is close to the mg L^{-1} level, so they are easily detected by GC detectors. When injecting wine in this way, the nonvolatile fraction remains in the injector and may be thermally degraded, giving rise to potential interfering substances (artefacts) and unstable baselines. Distillation of the volatile fraction or filtration, after addition of a water-miscible solvent to reduce the polarity of the wine matrix, helps to minimize this problem.

Injection after clean-up and concentration treatments is usually applied to the analysis of trace compounds ($\mu\text{g L}^{-1}$ to ng L^{-1}) to enhance their detectability. At the same time, interfering substances are removed during the isolation procedure. The main problems with these techniques are the occasional quantitative and qualitative changes of the analytes, the formation of artefacts by chemical reactions or thermal decomposition, and the introduction of impurities. For these reasons, the suitability of the isolation and concentration methods for a particular analyte has to be carefully evaluated.

Distillation is normally used to isolate the wine volatiles from the nonvolatiles. It can be carried out at atmospheric or reduced pressure in different distillation modes (direct, steam and fractional). By working at reduced pressure and low temperature chemical reactions or thermal decomposition can be minimized. The most important disadvantage is that the isolates obtained are diluted and it is necessary to combine the distillation with other methods that concentrate the volatile fraction.

Solvent extraction is used to simultaneously isolate and concentrate the volatiles. It is carried out in batch mode (simple or multiple) or continuous mode (by using continuous liquid-liquid extractors). The choice of the solvent is conditioned by the high concentration of ethanol (10–15%) in wines. Owing to their low boiling points and very low polarities, pentane, dichloromethane and their azeotropic mixtures are commonly used because they discriminate against ethanol. Other solvents used are diethyl ether and ethyl acetate. Fluorocarbons were widely used because of their extraction efficiency and very low boiling points, but nowadays they are environmentally

unacceptable. One of the disadvantages of solvent extraction is the use of large volumes of solvents (normally not free of contaminants) and the large amount of time spent in the extraction. Whenever possible, the use of minimum solvent/sample volume ratios enhances the concentration and minimizes contamination problems. At the same time, the efficiency of the extraction can be raised appreciably by salting-out the solution with sodium chloride.

The low boiling points of these solvents allow the concentration of the extracted volatiles by distilling off the solvent. By using a Kuderna–Danish concentrator the loss of volatiles is minimized. Furthermore, a gas stream is used to remove the solvent excess from the extract. This procedure is very effective, but may lead to the introduction of contaminants from the gas and to losses of the most volatile compounds.

Simultaneous distillation–extraction, using the apparatus originally described by Likens and Nikerson, has not been commonly applied to wine analysis. Supercritical fluid extraction is not common, but it is becoming increasingly accepted.

Solid-phase extraction (SPE) has also been used for the isolation of wine aroma compounds. The most common adsorbents are charcoal, silica gel and porous polymers (ChromosorbTM, PorapakTM, Amberlite XADTM and TenaxTM). The volatile compounds retained are usually eluted and/or fractionated by pentane, diethyl ether, dichloromethane, ethyl acetate or their mixtures. This technique is preferred for the analysis of a specific group of volatiles, since the adsorbent used is normally selective. Large volumes of adsorbents and solvents are used in order to assure the whole recovery of analytes, so dilute solutions are obtained. A final step including solvent evaporation is therefore needed.

Headspace techniques are widely used in wine aroma determinations because they enable the direct analysis of the headspace gas above the heated samples, where the compounds responsible for the aroma detected by the human nose are transferred. The static headspace technique is suitable for the analysis of the aromatic compounds of highest concentration, but for the analysis of trace levels it is necessary to use dynamic headspace (purge and trap) techniques. The retention of the volatiles is usually achieved by using either cryo or sorbent traps. Sorbent traps are normally preferred because the retention of water and ethanol is minimized, using the same adsorbents mentioned for SPE. The trapped volatiles are recovered by extraction with small volumes of solvent or by thermal desorption, which can be carried out in the chromatographic injector, enabling the overall sample to be analysed in a single step. On the

other hand, the volatiles obtained by solvent extraction are more dilute, but the sample can be fractionated and therefore injected in several chromatographic runs.

Solid-phase microextraction (SPME) is a single-step solvent-free extraction technique that combines the advantages of both SPE and headspace techniques. It has been increasingly applied to the isolation of flavour compounds. The adsorbent (usually polydimethylsiloxane-, divinylbenzene- or polyacrylate-coated fused silica fibres) is fixed in the needle of a specially designed chromatographic syringe and exposed either to the liquid sample or to the headspace above it. After exposure of the fibre to the sample, absorbed analytes are recovered from the fibre by thermal desorption in a conventional GC injection port.

Chromatographic Separation

The chromatographic separation is normally carried out in a gas chromatograph equipped with a split/splitless injector and a flame ionization detector (FID). On-column injectors with retention gaps are very useful for the analysis of traces because they enable the injection of large volumes of wine extracts and the concentration of the volatile fraction at the head of the chromatographic column. Programmed temperature vaporizer (PTV) injection is also suitable for the direct desorption of volatile compounds trapped on injector glass liners filled with adsorbents.

The detection of the analytes is usually carried out with a FID or a mass spectrometer detector (MSD). Other detectors are used only to detect more specific compounds. The flame photometric detector (FPD) and, more recently, the sulfur chemiluminescence detector (SCD), are widely used for detection of sulfur-containing compounds, mainly thiols, sulfides, disulfides and heterocyclic compounds. The electron-capture detector (ECD) is used to detect halogenated substances, such as chlorophenols and chloroanisoles, which are associated with cork taint off-flavours. The ECD and the nitrogen phosphorus detector (NPD) are widely used for the analysis of pesticide residues and some specific additives.

To characterize the wine flavour, gas chromatography–olfactometry (GCO) has been coupled with different methods that determine the relative aroma intensity. The smell of the different components of the wine aroma is assessed by sniffing the effluent of the chromatographic column in parallel with FID detection.

All kinds of chromatographic columns can be used to separate the volatile analytes of wines, but fused silica capillary columns with different stationary phases are the most common. Polyethylene glycol

phases are preferred for the evaluation of the global wine aroma, while less polar phases (such as methylsiloxane and methylphenylsiloxane phases) are needed for assessing the identification of individual compounds. Chiral phases are used for the separation of the enantiomers of volatile compounds, which exhibit very different sensory properties. Multi-dimensional gas chromatography is used for the analysis of volatiles that are not well separated with a single column.

Selected Applications

Many of the sources listed in the Further Reading section deal with the analysis of wines by GC. The following methods are usually performed in oenological laboratories for routine control and research studies.

According to the OIV method, the determination of methanol and ethyl acetate in wines is carried out by GC-FID. Wine distillates are injected in the split injection mode on a polyethylene glycol column under isothermal conditions. This method enables the simultaneous determination of other compounds present in the distillate, such as acetaldehyde, 1-propanol, 2-methylpropanol, 1-butanol, 2- and 3-methylbutanol, 1-pentanol, 1-hexanol, 2-phenylethanol, ethyl lactate, ethyl succinate, 3-methylbutyl acetate, acetic acid, some polyalcohols and so on. In routine analysis, this procedure is usually simplified when wines are directly injected. **Figure 1** shows an example of the chromatogram obtained under these conditions.

The main aroma compounds of wine distillates are analysed by direct split injection of samples with

a temperature programme that optimizes the separation of the different substances. The compounds determined in wine distillates by this OIV method are methanol, acetaldehyde, acetals, higher alcohols, ethyl esters of fatty acids, acetates of the main alcohols and volatile fatty acids. There are other aroma compounds that can be detected by splitless injection of the extract obtained with a batch extraction using ether/hexane (1 : 1) and magnetic stirring. **Figure 2** shows an example of the chromatogram obtained when a methylene chloride wine extract is injected.

In research work, the isolation of the global aroma of wine is usually performed by continuous solvent extraction using different ratios of pentane-dichloromethane and different times of extraction. The extract is dried over anhydrous sodium sulfate and concentrated either in a Kuderna-Danish device or with a gas stream. The concentrate is injected into the GC-FID, working in splitless mode and with a programmed column temperature. Purge and trap methods are suitable alternatives to this procedure and, more recently, SPME has also found some applications in the determination of the ethyl esters of spirit beverages and in the analysis of the main aroma of fruit juices.

Currently, many other volatile compounds are investigated by GC for their sensory contribution. The most important are terpenes, lactones (solerone, sotolone and oak lactones), carbonyl compounds (hexenals, β -damascenone and α - and β -ionone), volatile phenols (alkylphenols and alkylguaiacols), thiols, sulfides, disulfides, pyrazines and vitispiranes. The particular methods of analysis for these compounds are fully described in publications listed in Further

Reading. Two examples of chromatograms obtained from the analysis of sulfur compounds (**Figure 3**) and pyrazines (**Figure 4**) are shown.

High Performance Liquid Chromatography (HPLC)

The first studies on the application of HPLC to the analysis of wines appeared at the end of the 1970s for the analysis of polyphenols. Since then, HPLC has been applied to the separation, characterization and determination of a large number of wine compounds

or groups of compounds. The literature concerning the application of HPLC in wine and must analysis is very extensive, but it is important to emphasize the particular interest of this technique in the study of polyphenols, amino acids, biogenic amines, organic acids and sugars.

The use of HPLC is rarely recommended in the official methods. However, carboxylic acids, saccharose, hydroxymethylfurfural and some additives such as sweeteners can be determined by official HPLC methods.

As mentioned above, one of the main problems when dealing with wines is the complexity of the matrix. Although HPLC offers the possibility to choose columns, solvents, detectors and derivatizing reagents, many of the chromatographic procedures developed for HPLC determinations in wines involve some kind of sample pretreatment. These procedures generally make use of either ion exchange

chromatography and/or solvent of solid-phase extraction.

Sample Preparation

Filtration of samples through a 0.45 μm membrane is always recommended before injecting wines into the HPLC system. This process can be before or at the same time as more complex pretreatments.

One of the methods for avoiding the presence of interfering substances is eluting wine through a low pressure liquid chromatographic column. Polyvinylpyrrolidone (PVP), polyvinylpolypyrrolidone (PVPP) and polyamide adsorbents are used to eliminate polyphenolic substances and silica is used to retain proteins. Ion exchangers are commonly used either to clean up samples or to isolate ionized amines and organic acids from wines.

The most common method used to pretreat samples is solvent extraction with ether or ethyl acetate, although many researchers use more selective solvents.

Solvent extraction has generally been replaced by SPE and SPME. Although there are some applications of carbon and ion exchange cartridges, octadecylsilane (C_{18}) is the most commonly used adsorbent. Many of the analytes whose determination in wines is of interest (such as polyphenols, amino and aroma compounds) can be selectively retained or eluted with slight modifications of matrix conditions (such as pH or addition of ion pair reagents) or by transforming the analytes by derivatization.

Chromatographic Separation

Reversed stationary phase (RP) are the most popular in the HPLC analysis of wines, although it is fully recognized that they are not capable of separating all kinds of analytes in wine. Apart from some special applications, silica is utilized almost exclusively as the support material and C_{18} as the bonded phase.

Since wines are constituted of analytes spanning a wide range of polarities, linear solvent strength gradients are preferred for analysis. Mobile phases normally consist of binary mixtures of either methanol or acetonitrile and slightly acidified water.

The variable UV-visible (UV-vis) wavelength detector is the most popular, although fluorescence and refractive index detectors are also common. Photodiode array detection has also found some application.

Selected Applications

In contrast to GC, the analysis of wines by HPLC has focused on determining compounds with similar chemical functionality.

Figure 5 Chromatogram of free amino acids in white wine after derivatization with PITC and DAD detection. (Reproduced with permission from Calull M, Fàbregas J, Marcé RM and Borrull F (1991) Determination of free amino acids by precolumn derivatization with phenylisothiocyanate. Application to wine samples. *Chromatographia* 31: 272–276.)

Ion exchange chromatography has become the most popular technique for the determination of amino acids due to the use of autoanalysers. After chromatographic separation, the analytes are derivatized with ninhydrin, fluorescamine or *o*-phthalaldehyde and detected by spectrophotometry. Amino acids can also be determined by RP-HPLC, which is faster than ion exchange chromatography. The stationary phases are based on amino and, especially, C_{18} chemical groups. Although isocratic elution is used in some applications, gradient elution is preferred because it enables the simultaneous determination of amino acids of different polarities. Mobile phases are normally of binary composition (methanol or acetonitrile and an aqueous buffer solution). As in ion chromatography methods, the amino acids are derivatized, but this time dansyl chloride or phenylisothiocyanate (Figure 5) are used for UV-vis detection and *o*-phthalaldehyde for fluorimetric detection.

Amines are also determined by HPLC, either by direct injection or, more commonly, by derivatization. When they are directly injected, they are separated by ion pair chromatography on a C_{18} column and detected by conductimetry or spectrophotometry. The main limitation of these procedures is that mobile phases shorten the life of the column, so procedures involving the separation of derivatized amines are preferred. Ninhydrin is one of the reagents commonly used in post-column derivatization. The separation is done either by RP-HPLC or by ion exchange chromatography. However, these methods are very time-consuming and so pre-column derivatizations are preferred. The derivatizing reagents used in this case are the same as when dealing with

Figure 6 OPA-derivatives of biogenic amines in red wine after SPE and fluorescence detection. Copyright 1995, Elsevier Science.)

amino acids, *o*-phthalaldehyde being the most used (Figure 6). The derivatives are separated by RP-HPLC and detected by spectrophotometry or fluorimetry.

Although carboxylic acids can be determined by GC, after suitable derivatization, the OIV proposes the use of HPLC for determining carboxylic acids in wines, as an alternative to the usual enzymatic procedures. RP-HPLC is used either by direct injection of the wine or by derivatization of the acids before separation. Direct injection of carboxylic acids is a simple method, but the use of mobile phases at low acidic pH (to avoid acid ionization) considerably reduces the life of the analytical column, hence derivatization is recommended. Furthermore, when acids are transformed into their corresponding esters, detection is more sensitive. The different derivatization methods reported so far for the determination of organic acids with spectrophotometric detection and which are worthy of special mention are those which use organic compounds containing the chromophore groups phenacyl, naphthacyl and *p*-nitrobenzyl. The organic groups containing coumarin and anthracene groups, on the other hand, are used for fluorimetric detection. Mobile phases are of binary solvents (normally methanol and water) and the elution is done isocratically or with a linear gradient.

Anion exchange chromatography is an alternative to RP-HPLC, using mobile phases made of organic

Figure 7 Chromatogram of a wine obtained by high resolution ion exclusion chromatography and refractometric detection. Key: 1, citric acid; 2, tartaric acid; 3, glucose; 4, malic acid; 5, fructose; 6, acetic acid; 7, glycerol; 8, lactic acid; 9, methanol; 10, ethanol.

solvents buffered at a pH close to 8 and with conductimetric or refractometry detection. Although good results are obtained by this method, ion exclusion chromatography using strong cation exchange phases has become the best technique. There are stationary phases specifically developed for determining carboxylic acids in fermented products, which permit the simultaneous determination of sugars, ethanol, methanol and glycerol in a single run. Mobile phases consist of slightly acidic water solutions and the detectors used are either UV or refractive index. Figure 7 shows an example of the chromatogram that is obtained when wine is directly injected under these conditions.

Some papers have reported the separation of carboxylic acids by NP-HPLC and ion pair chromatography, but the results are not comparable to those obtained from the methods described above.

Although the official methods of analysis of sugars are based on enzymatic techniques, sugars can also be determined by HPLC. The preferred methods are based on the use of specific ion exclusion polymeric columns because they enable the simultaneous determination of carbohydrates and other analytes, as already mentioned. The mobile phase used is dilute sulfuric acid and the detection is carried out by spectrophotometry or refractometry. RP-HPLC of sugar benzoylated derivatives followed by spectrophotometric detection has also been used to determine carbohydrates in wines (Figure 7).

According to the OIV methods, saccharose is analysed by HPLC. In this case, the column used is based on 3-aminopropylsiloxane-bonded phases and the mobile phase is acetonitrile and water with refractive index detection.

There are classical methods for estimating the total phenol content of wines, but HPLC is necessary for the determination of individual polyphenolic

compounds. Chromatographic procedures are conditioned by the lack of suitable standards and the complexity of chromatograms. Thus, the determination is tackled from the point of view of the two different families of phenolic compounds: flavonoids (anthocyanins, flavanols and procyanidins), and non-flavonoids (hydroxycinnamic and hydroxybenzoic derivatives). Nevertheless, only the pretreatment of samples is different depending on the fraction that has to be isolated. HPLC on reversed-phase columns is almost universally used for anthocyanin separation. The most common used support is C_{18} . Extremely acid solvents are required to suppress ionization of the analytes. Solvents such as methanol/water and acetonitrile/water (in varying propor-

tions), acidified at low pH with phosphoric, perchloric or formic acid, have been used with different solvent programmes. When dealing with flavonols and procyanidins, extraction and purification of wines prior to HPLC is needed. HPLC analysis of flavonols is achieved on C_{18} columns with binary solvent systems consisting of acetonitrile and acetic acid in water and using gradient elution programmes. Procyanidins are chromatographed on C_{18} , C_8 or cyano columns and dilute acid is normally required as a component of the solvent to obtain satisfactory peak shapes. Hydroxycinnamic acids are also analysed by HPLC, by using C_{18} columns and methanol/water eluents slightly acidified with acetic acid. In all cases, detection is carried out spectrophotometrically (Figure 8).

Other substances which are present in wine but which are not determined as frequently as the ones discussed above can also be determined by HPLC. These include additives such as sorbic, salicylic, benzoic and ascorbic acids, which can be determined, according to OIV methods, by RP-HPLC coupled with either spectrophotometric or refractive index detectors.

Future Trends

Both GC and HPLC techniques are widely used in wine analysis. Although the methodologies are normally based on traditional separations, multidimensional chromatographic methods (with or without chiral phases) are increasingly being introduced, frequently coupled online with other analytical devices. More recently, capillary electrophoresis and supercritical fluid chromatography have also been used for wine determinations, but they are still in an early stage of application.

At present, most of the chemical compounds present in wine can be determined by means of a great variety of chromatographic methods described in the literature. Future trends, however, will focus more on internal method validation rather than on development of new methodologies. Future official methods of analysis will then include the minimum requirements (accuracy, precision, limit of detection, robustness, and so on) that an analytical method must fulfil in order to guarantee the validity of the results obtained.

ZEOLITES: ION EXCHANGERS

C. D. Williams, University of Wolverhampton, Wolverhampton, UK

The ion exchange properties of zeolites have been known since 1858, when Eichhorn studied the use of chabazite as an ion exchanger. In the 1920s and 1930s several ion exchange studies were reported.

During the 1960s many groups studied the ion exchange behaviour of the new synthetic zeolites then being produced. Due to the enormous commercial potential of zeolites, many research groups worldwide began serious efforts to synthesize new microporous zeolites and zeotype materials. The first major breakthrough was made by workers at Union Carbide, who in 1982 produced the aluminophosphate molecular sieves (Table 1). Although these materials are electrically neutral and have no intrinsic ion exchange properties, they did lead to the development

of other substituted aluminophosphates that do have ion exchange properties (Table 2).

Since the early 1980s several new zeotypes, based on oxoanion frameworks, have been developed. The major group of materials of interest as far as ion exchange properties are concerned are the layered group IV acid salts. These include phosphates, arsenates, molybdates, tungstates, antimonates, silicates and silicophosphates. Most of these materials act as cation exchangers. Early attempts at synthesis mimicked zeolite preparations using reactive amorphous gels crystallized at temperatures between 120 and 200°C. This crystallization produced a variety of materials, which have been classified by their structure type: α -layered exchangers, γ -layered exchangers, fibrous exchangers, 3-D net exchangers and unsolved structure exchangers. Table 3 lists some of the more important α -layered ion exchangers.

The structure of αZrP was determined by Clearfield in 1969. The inorganic layers are formed by a plane of octahedral Zr atoms that are linked together alternatively above and below via phosphite groups. Three oxygen atoms of the phosphite group are coordinated in this way and the fourth bears a hydrogen atom (Figure 1).

Table 3 Important α layered ion exchangers

Compound	Formula	Interlayer distance (\AA)	Ion exchange capacity (mmol g^{-1})
Titanium phosphate	$\text{Ti}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.56	7.76
Zirconium phosphate	$\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.56	6.64
Hafnium phosphate	$\text{Hf}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.56	4.17
Germanium phosphate	$\text{Ge}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.6	7.08
Tin(IV) phosphate	$\text{Sn}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.76	6.08
Lead(IV) phosphate	$\text{Pb}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	7.8	4.79
Titanium arsenate	$\text{Ti}(\text{HAsO}_4)_2 \cdot \text{H}_2\text{O}$	7.77	5.78
Zirconium arsenate	$\text{Zr}(\text{HAsO}_4)_2 \cdot \text{H}_2\text{O}$	7.78	5.14
Tin(IV) arsenate	$\text{Sn}(\text{HAsO}_4)_2 \cdot \text{H}_2\text{O}$	7.8	4.80

The α ZrP exchangers have been characterized by carrying out potentiometric titrations against MCl and MOH solution mixtures. X-ray analysis of the solid phases shows that α ZrP is initially converted to $\text{ZrMH}(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$ then on further exchange is converted to $\text{Zr}(\text{MPO}_4)_2 \cdot n\text{H}_2\text{O}$. At any point during the ion exchange process these two phases coexist together with the solution phase. The interlayer distance is large enough to accommodate unhydrated Li^+ , Na^+ and K^+ ; however Rb^+ and Cs^+ are too large to enter without lattice expansion. The energy to expand the lattice is supplied by a base, neutralizing the lattice protons and allowing larger cations to enter.

The γ -layered compounds are far less common than the α compounds. Both $\gamma\text{ZrPZr}(\text{HPO}_4)_2 \cdot 2\text{H}_2\text{O}$ and $\gamma\text{TiTi}(\text{HPO}_4)_2$ are known, but both suffer from hydration at high exchange levels. Both materials have large interlayer distances and as a consequence can accept large cations such as Cs^+ .

Pastor *et al.* have reviewed the synthesis, characterization and ion exchange, ion transport, sorptive and catalytic properties of inorganically pillared layered metal(IV) phosphates, typified by $\text{Zr}(\text{BPO}_4)_2 \cdot \text{H}_2\text{O}$. Porous nanostructures are generally prepared from metal(IV) phosphates either by ion exchange of polynuclear species or by intercalation from solutions of

condensed species obtained by the hydrolysis of organometallic precursors using sol-gel methods. Thermal treatment is used to eliminate organic moieties, condense hydroxyl groups, eliminate water and consolidate the structure by grafting the pillar to the layer. The different strategies devised to overcome the problem presented by the high layer charge density of α - and γ -structured phosphates in obtaining porous solids are described, including exfoliation and local surface growth of pillaring ions, and modification of the zirconium phosphate matrix in order to reduce the cation exchange capacity. Structural and textural characteristics of Al, Cr, mixed Al-Cr, Fe-Cr, Ga-Al and of Si-pillared phosphates obtained from X-ray analysis by fine structure (XAFS), X-ray photoelectron spectroscopy (XPS), and magic angle spinning nuclear magnetic resonance (MAS-NMR) are presented, and the perspectives of nanocomposite pillared layered solids in general are discussed in the current context of mesoporous solids synthesized using templates.

The fibrous materials are exemplified by cerium and thorium(IV) phosphates. Their fibrous nature allows them to be fabricated into papers that allow fast separation of cations. The precise structure of these phosphates is unclear but is probably $\text{M}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, where $\text{M} = \text{Ce}$ or Th .

**Figure 1** Structure of α Zr-P.

The three-dimensional materials have the general formula $NM_2(IV)(XO_4)_3$, where M(IV) is Ti, Zr, Th or Ge; X is P or As and N is a univalent cation. The structures consist of XO_4 tetrahedra and $M(IV)O_6$ octahedral linked by corner sharing to form 3-D networks; this linking forms cavities, occupied by N^+ . If phosphate is progressively replaced by silicate the cavities open up, allowing free movement of the N^+ cations and leading to the cation exchange properties. Numerous specific examples of these materials can be found in the literature, particularly the gallium phosphate-derived materials.

A more recent series of exchangers are those of the titanosilicate type, which have zeolite type pores/cavities. The materials have a formula $Na_2Ti_2O_3SiO_4 \cdot 2H_2O$ and are synthesized from an alkaline medium under similar conditions to those used to crystallize zeolites. The structure has been solved using Rietveld refinement and shows titanium atoms in clusters of four, octahedrally coordinated by oxygen atoms. The silicate groups link the titanium clusters into a square which then shares corners with other titanium cluster squares to form a 3-D network. Half of the sodiums are linked into the framework while the other half are labile and available for ion exchange.

In 1991 a zincosilicate containing three-, four- and five-member rings connected together to form a porous eight- and intersecting nine-member ring channel was reported. Initial studies indicate that the labile monovalent cations can be exchanged.

A great deal of synthetic work has been directed at replacing the aluminium in various zeolites with other metals/nonmetals, including the crystallization of ferrisilicates, borosilicates, gallosilicates, vanadosilicates and titanosilicates. In 1992 the synthesis of a zincophosphate anionic eight-ring three-dimensional framework was reported. During the synthesis the anionic framework was stabilized by cationic, protonated diazabicyclo[2.2.2.]octane or dabco $[(H_2N_2C_6H_{12})^{2+}]$ molecules and water. These materials, although chemically similar to Clearfield's layered phosphates/phosphites, benefit from having a stable open 3-D structure. No ion exchange data has been given but thermal analysis shows that the framework is stable even after the organic dabco has been removed. This calcined material has potential as a cation exchanger. In 1991 the synthesis of sodium zirconium phosphate with a zeolite-type framework was reported. The synthesis followed typical aluminophosphate preparations using triethylamine as a template. The synthesis was carried out in an acidic medium, resulting in the template becoming protonated. Once crystalline, the sample had the template removed by calcination and the adsorption properties of the new material were studied. The

material remained microporous after calcination; however, no ion exchange studies were carried out. Initial studies suggest that this material would act as a cation exchanger.

However, although an enormous number of new materials have been synthesized since 1990, there are few reports on the ion exchange characteristics of these materials.

Future Developments

Over the past five years increasing emphasis has been placed on the investigation into microporous materials based on oxoanion networks other than the aluminosilicates (zeolites). The vast array of microporous materials with potential ion exchange properties is enormous. The number of reported nonzeolite molecular sieves now tops 130. The range of materials includes gallosilicates, borosilicates, ferrosilicates, germanium aluminates, titanosilicates, silico alumino phosphate (SAPO) and metal alumino phosphate (MeAPO) molecular sieves. Most of these new materials have not yet been characterized for their ion exchange properties. The potential of these materials is as yet unrealized but, with increasing environmental demands, it is only a matter of time before these materials are explored.

ESSENTIAL GUIDES FOR ISOLATION/PURIFICATION OF CELLS

J. Bauer, Max-Planck-Institut für Biochemie,
Martinsried, Germany

Copyright © 2000 Academic Press

In cell-separation technology the term 'component' of a mixture corresponds to a group of cells, which is usually called a cell population and shares a number of common features. How many common features a group of cells has to share in order to be called a cell population depends on the interest of the 'separator'. For example, a T-cell population may be a group of mononuclear white blood cells bearing CD3 antigens, while a helper cell population usually comprises mononuclear white blood cells bearing CD3 and CD4 antigens.

Cells metabolize as long as they live independently, whether they remain in an actual state of activation or differentiation or they proceed to another one. This means that a whole cell must not change its appearance or functions, but some cell components are chemically modified either anabolically or catabolically. So for discussing cell separation the term 'chemical modification' should be converted to 'biological modification' and in this chapter the expression 'without biological modification' will be defined as purification of cells without changes or signals for changes of cellular states of activation and/or differentiation.

No technology has been developed so far which allows picking of cell populations directly out of pieces of plant or animal tissues. So a 'mixture' which will be separated is normally a suspension of single cells prepared from parts of plants, from organs or body fluids of animals and humans or from two- or three-dimensional *in vitro* cell cultures. These cell sources already contain preselected groups of cells, the so-called organ or fluid (e.g. blood) specific cells. Still, a series of populations differing in important features are present in most plant or animal body compartments. In these instances, it may be of interest to separate cells for studying their biology or for using some of their capabilities in medicine or biotechnology.

Thus the following reflections on essential guides for separation/purification of cells are based on separations defined as processes of any scale by which cell populations of single-cell suspensions are separated from each other without biological modification.

Methods for Cell Separation without Biological Modification

The above definition rules out some technologies, frequently used to prepare homogeneous cell populations, because they include biological modifications of cells. For example, the enrichment of cell types of interest by establishing cell lines or cell clones will not be considered as a subject in this chapter. Cell lines or cell clones may be very useful sources of important genes and gene products. However, their cells are transformed in unnaturally fast growing states, in order to separate them from unwanted accompanying cells. Also cell separation/purification techniques using different capabilities of various kinds of cells to adhere to surfaces of, for example, culture dishes or fibres or to bind antibodies or macromolecules labelled by fluorescence dyes or magnetic beads, will not be described, because cell interactions with foreign components or antibody binding sites very often induce biological modifications. Of course, cell-purification methods like those mentioned above are very useful in research and biotechnology. The reader may find more informations regarding these techniques in the Further Reading.

This chapter focuses on application of counter-current centrifugal elutriation (CCE) and free-flow electrophoresis (FFE). These methods use differences of physical cell parameters such as specific cell density, cell size or negative surface charge density but do not include steps of cell labelling or cell transformation. They have the advantage that cells can be purified within a short time while they are kept suspended in biocompatible fluids or even culture media. Cell contacts to foreign surfaces and/or biologically active substances are thereby minimized and signals of activation and differentiation are delivered to cells during the isolation procedure to a minimal extent. Both methods may help to obtain sufficient numbers of identical cells with a high degree of purity and vitality for studying the biological role, which a defined cell population may play within an organism or for transplantation of cells with states of activation and differentiation suitable to fit in the new organism of a recipient.

Single-Cell Suspensions

Up to the present, cell separation by physical methods has required single-cell suspensions. Some cell

compartments such as peripheral blood, ascites, lymph or other body fluids already contain single cells. Cells of organs such as bone marrow, spleen or thymus can easily be removed, for example with the help of needles. The dissociation of single cells from two- or three-dimensional tissue cultures and from solid body tissues needs more rigorous methods. These cells not only adhere to each other, but are also more or less firmly attached to the extracellular matrix, a complex network of collagen, proteoglycans and cross-linking proteins such as laminin and fibronectin. Mechanical dissociation by scraping cell monolayers from their surfaces or by forcing tissue pieces or cell aggregates through orifices or syringes or pipettes very often damages the cells and results in a poor yield. An enzymatic treatment or pretreatment of cell cultures or organs is thus often applied in order to digest the extracellular matrix and/or to weaken the cell-cell attachment sites. The selection of the enzymes, their concentration and their time and temperature of application depend on the type of organ and its originating organism. Enzymes frequently used for animal cell preparation are collagenase, trypsin, pronase, dispase, papain, chymotrypsin, hyaluronidase, lysozyme and DNase, while cellulase is a typical enzyme for plant tissue dissociation. Sometimes the action of the enzymes is supported by the presence of EDTA (ethylenediaminetetraacetic acid), which destroys binding sites mediated by Ca^{2+} ions. Details regarding techniques of preparing single cells may be found in books quoted in the Further Reading. In general, the enzymatic treatment has to be optimized for each cell-separation process, because the enzymes may not only attack cell membrane components which keep the cells within the tissue but may also destroy important cell-membrane functions.

If neither mechanical nor enzymatic methods lead to satisfactory results, an alternative way may be to incubate pieces of tissue on surfaces which challenge the cells to move out of the tissue and to form monolayers surrounding the tissue. For example, cells of human prostate tumour sections, which cannot be dissociated in viable single cells by a number of mechanical and enzymatic techniques, migrate out of the tissue and form a monolayer, when incubated in culture dishes for a few weeks. After removal of the tissue, the cells can easily be scraped off the plastic dish surface.

Pre-Separation

As soon as single cells are available, countercurrent centrifugal elutriation or cell electrophoresis may be applied. However, some cell-separation tasks need pre-enrichment of the cells of interest. Especially

where an investigator is interested in a peripheral blood leukocyte population such as a lymphocyte, granulocyte, monocyte or even reticulocyte population, the erythrocytes comprising more than 99% of the blood cells have to be removed before one of these white blood cell populations may be purified. In these instances, it has proved useful to perform a first step of density-gradient centrifugation, which does not need pre-labelling of cells. The method allows the separation of mononuclear leukocytes consisting mainly of lymphocytes and monocytes from granulocytes and erythrocytes. The separation principle is based on different specific densities of the various cell populations. In practice, a tube is filled with a biocompatible isotonic medium with a specific density adjusted between the specific densities of the cells to be separated and the cell mixture is layered on the top of this medium. Then the whole sample is exposed to a few hundred g by centrifugation. The forces cause mononuclear leukocytes with a density lower than the separation medium to remain at the top, while those with higher density sediment to the bottom. The specific density of the medium is adjusted by silica colloids, which are coated with an inert material and have low osmolality. Although modern commercially available density-gradient separation media are very inert and direct damage of the cells is seldom observed, the silica colloids are pinocytosed by some cells.

If this is a problem, prolonged centrifugation of whole blood may be an alternative route. During such a centrifugation procedure, a layer of white blood cells is formed above the erythrocytes. This layer, called a buffy coat, contains mononuclear as well as polymorphonuclear leukocytes and lies directly on the erythrocytes. The white cells may be collected. Although co-collection of a considerable number of red cells is usually unavoidable, a degree of white blood cell pre-enrichment can be achieved which allows reasonable further separation by, e.g. CCE.

Countercurrent Centrifugal Elutriation (CCE)

The method of CCE and the equipment required for cell separation according to cell size have already been described so they are summarized only brief here. Cells loaded into the elutriation chamber are subjected to centrifugal sedimentation forces generated by rotation in an outward direction and to counterflow fluid forces pumped into the separation chamber in an inward direction. As long as sedimentation forces are balanced by the opposite fluid forces, different cell populations take different chamber positions depending mainly on their sizes

Figure 1 Table-top elutriator (middle) together with an infusion pump driving the counterflow (left) and a volume analyser (right).

and to a lesser extent on their specific densities. If the counterflow rate is increased by speeding up a pump and/or the sedimentation forces are decreased by reducing centrifugation velocity, the various cell populations are washed out sequentially with increasing size ranges.

Commercially, small elutriation chambers with 5 mL separation volume and large ones with 40 mL are available together with suitable centrifuges and rotors from Beckman Instruments (Palo Alto, USA). They can accommodate up to 10^9 and 10^{10} cells, respectively. A laboratory device has also been constructed; it consists of a table-top centrifuge with a small rotor which has a separation chamber with a volume of 0.5 mL to which 10^6 tissue cells or 2×10^7 mononuclear leukocytes may be loaded (Figure 1).

In order to fractionate cells with different sizes into different fractions, counterflow rates and rotor speeds have to be adjusted depending on rotor size, chamber volume and the size of the cells to be separated. The result of each separation should be controlled by recording volume distributions of the cells of each fraction with the help of cell size analysers. Beckman

rotors are frequently operated at speeds ranging from 1000 to 4000 rpm. Dependent on the actual rotor speed, the counterflow through small chambers may be started at rates between 8 and 20 mL min⁻¹ and increased for fractional elution stepwise up to 100 mL min⁻¹ (Table 1); counterflow rates through large separation chambers may start at 50 mL min⁻¹. The table-top centrifuge is operated at counterflow rates between 1 and 6 mL min⁻¹, while the rotation speeds are between 500 and 2200 rpm for tissue cell separation and between 1500 and 2800 rpm for leukocyte separation (Table 2). Using any of the instruments, separation times are short and the cells may be kept suspended in culture medium. Thus unwanted exposure of the cells to stimulatory environments are minimized so that characteristics of separated populations will rather closely reflect the status of the original cells before fractionation.

Because of these advantages, CCE has proved most useful, if applied for the separation tasks listed below:

- For cell cycle analyses, the cellular DNA content is normally determined. However, cells have to be killed in order to make their DNA accessible for intercalating fluorescence molecules. If living cells in different steps of the cell cycle need to be separated, an increase of cell size during passage through the cell cycle may be used as a separation parameter. With the help of CCE the small cells, which are in G1 phase can be separated from S-phase cells which have intermediary size and from the G2/M-phase cells which have the largest size of the cell population. Many flow cytometric analyses of the DNA content of separated cells have already proved that CCE enables the separation of cells of cell lines in fractions, which have up to 100% G1 phase cells, up to 80% S-phase cells and up to 80% G2/M phase cells, respectively.
- A number of different kinds of cells such as mononuclear phagocytes recognize very non-specifically

Table 1 Examples of counterflow and rotor speed adjustments using a Beckman elutriator equipped with JE-6 rotor (small separation chamber)

Cell mixtures:	sheep erythrocytes/reticulocytes	human mononuclear leukocytes	cultured human lymphocytes/macrophages
Pre-enrichment:	buffy coat	density-gradient centrifugation	none
Cell size range:	28–42 μm^3	180–400 μm^3	180–2000 μm^3
Rotor speed:	3000 rpm	2460 rpm	2460 rpm
Counterflow:	9–24 mL min ⁻¹	16.5–40 mL min ⁻¹	16.5–81 mL min ⁻¹
Desired cells:	reticulocytes	lymphocytes/monocytes	macrophages
Eluted at:	24 mL min ⁻¹	22 mL min ⁻¹ /40 mL min ⁻¹	80 mL min ⁻¹
Use:	analysis of volume regulation	further enrichment, immunological tests	surface charge analysis

foreign molecules and particles entering an organism. So despite many alternative methods such as antibody-dependent sorting or panning, CCE, which does not involve cell adhesion to matrices or to antibodies, is often preferred, to separate monocytes from peripheral blood or bone marrow and to purify macrophages from alveolar tissues or Kupffer cells from liver and to enrich mast cells, if contacts to stimulatory surfaces and substances must be avoided.

- Problems still exist in the detailed study of the biological and physiological features of healthy and malignant animal tissue cells and plant protoplasts. These cells have not yet been characterized, as well as, for example, lymphoid cells. Antibodies against the surface epitopes of such cells are not isolated in great abundance, so fractionation of single-cell populations, obtained from tissues of various organisms, by CCE, is a competitive way to provide important homogeneous cell populations for biological, toxicological and pharmacological studies.
- CD34-positive hematopoietic stem cells are very helpful to restore hematopoiesis of patients, who have to undergo whole-body radiation or rigorous chemotherapy. In the past, CD34-positive cells were separated either by panning, immunomagnetic sorting or fluorescence-activated cell sorting. All these techniques include expensive time-consuming steps of labelling cells by antibodies and generate problems of removing the antibodies/ligands from the surface of the purified cells. CCE thus appears to be an alternative method for CD34-positive stem cell purification as the stem cells have a similar volume as mononuclear leukocytes. However, resolution improvements still seem to be necessary.

Free-Flow Cell Electrophoresis (FFE)

Another method for purifying cell populations without antibody tagging or cell adherence is free-flow

electrophoresis. Its basic principle has already been described and is repeated briefly here. A laminar buffer stream flows between two narrowly spaced parallel glass plates forming a separation chamber. Near one end of the chamber, a cell suspension is injected as a narrow band into the fluid flow which carries the cells through an electric field applied perpendicularly to the carrier fluid flow. Cells exposed to the electric field migrate laterally towards the positively charged electrode with velocities depending on their negative surface charge densities. Thus cells with different negative surface charge densities migrate at different speeds, arrive at different points along the opposite edge line and can be collected for preparative isolation.

This principle is called ‘free-flow zone electrophoresis’ (FFZE) and is still the only electrophoresis mode applicable to cell separation, although it has poorer resolution than other electrophoresis modes such as isoelectric focusing (IEF) and isotachopheresis (ITP), because it is a non-focusing process. In addition, most whole cells do not tolerate a fluid pH below 6.9 and above 7.5 and need media which allow reasonable electrophoretic mobilities, but are simultaneously biocompatible. So for quite a long time, cell electrophoresis was rarely applied, particularly as resolution was often not high enough to purify cell populations with different mean electrophoretic mobilities but overlapping distribution curves and this second drawback negatively influenced cell vitality. Cells had to be suspended in media lacking NaCl or other physiologically important ions, because too many ions in the chamber medium caused problems of performance such as overheating of the medium and short electromigration distances, as long as only conventional devices with homogeneous chamber media were available.

Recently, a new type of FFE was developed which opened new possibilities of electrophoretic cell separation. It is called Octopus and is commercially available from the Dr. Weber GmbH, Kirchheim, Germany (Figure 2). It is quite suitable to perform

Figure 2 An Octopus free-flow electrophoresis apparatus with the electrophoresis chamber in vertical position (left) and implements such as a power supply, a pump and the control unit (right). (A generous gift of the Dr. Weber GmbH, D-85551 Kirchheim, Germany. More information about the machine may be found at <http://members.aol.com/ffeweber/default.htm>.)

preparative cell electrophoresis but can easily be adjusted to IEF and ITP of sub-cellular particles or molecular substances. Its electrophoresis chamber has a length of 500 mm and a width of 100 mm and can be fixed in a vertical or a horizontal position, as long as specimen sedimentation does not play a role. The thickness is variable, between 0.4 mm and 0.2 mm, so that heat-removal efficiency may be enhanced, if ions are required in cell suspension media and the application of high electric fields is necessary. An optical particle detection system allows control of process stability.

The major advantage of the new system is that various media may flow through the chamber adjacent to each other and the sample may be introduced at the optimal site (Figure 3). This means for cell electrophoresis, that one central cell suspension medium, which may contain up to 50 mmol L^{-1} NaCl is pumped between two margin media with elevated quantities of ions flowing at both edges (Table 3). They cover the electrode membranes, protect the separation medium from detrimental influences of the electrodes, prevent diminution of Na^+ and Cl^- ion concentrations within the central chamber area and conduct the electric current to this area of cell transport with minimal voltage drop.

Like CCE, FFE is most advantageous if antibodies coupled to fluorescent dyes or magnetic beads are not

available or must not be applied. So the method is quite useful, when cells are separated by CCE because of the reasons explained above and the resulting fractions still contain cells which belong to different populations, but have equal size, while their electrophoretic mobilities are different. For example, cell fractions are routinely obtained, which contain more than 90% monocytes, if pre-enriched mononuclear leukocytes are elutriated. In such fractions, up to 0.2% antibody-producing cells with equal size as monocytes but different electrophoretic mobilities (EPM) are often co-collected. The antibody-producing cells can be further enriched by FFE. Similarly, T-cell fractions obtained by CCE contaminated by accessory cells, of equal size have been submitted to a following step of FFE purification. T-cells of individual blood donors were obtained, which did not respond to concanavalin A unless accessory cells were re-added.

A cell feature, which cannot be defined by antibodies is the negative surface charge density. Its biological role is still very poorly understood. Observations made during recent cell electrophoretic studies appear currently like very scattered mosaic stones which do not allow the whole picture to be revealed. For example, erythrocytes change their EPM in patients suffering various kinds of diseases, monocytes change their EPM when maturing to non-activated macrophages, B-cells change their EPM when developing to antibody-producing cells *in vivo* but not *in vitro*, and mice with different erythrocyte EPM have different sensitivities to malaria infection (see Further Reading). These accumulating data suggest that further efforts in studying the biological relevance of the negative surface charge density by FFE will be worthwhile.

Since electrophoresis media with $20\text{--}50 \text{ mmol L}^{-1}$ NaCl can be used for cell separation, tissue cells can be processed without clotting. Now it is possible to electrophorese cell suspensions obtained from tissues directly or indirectly after a few passages of culture. The separations performed so far have revealed quite interesting new tissue cell sub-populations. Hence, future application of FFE to fractionation of viable tissue cells appears promising.

Conclusions

Essential guides for separation/purification of cells have been described in this chapter following a definition of cell separations as processes of any scale by which cell populations are separated from each other without biological modification, i.e. without changes of their actual states of activation and differentiation. As explained above and shown in Figure 4 single cells

Figure 3 Scheme of free flow electrophoresis chambers working with homogeneous (left) and segmented (right) carrier fluids.

suspended in suitable media after preparation from human or animal body fluids, from human, animal or plant tissues or from *in vitro* cultures are prerequisites of such processes. If a cell suspension with a reasonable number of desired cells is available, methods such as countercurrent centrifugal elutriation and free-flow electrophoresis may be applied, either each

of them alone or in combination. As both cell-separation methods are rapid and work while cells are kept in suspensions with minimal contact with foreign surfaces but do not require labelling of cell surfaces by antibodies or other macromolecules, a fair chance can be expected to obtain homogeneous cell populations retaining their original states of activation and

differentiation, even if appropriate antibodies are not available.

Cells purified without biological modifications may be especially useful if it is of interest to study their original *in vivo* status or to use them for transplantation purposes and if size or surface charge-related phenomena are to be investigated. As knowledge of possible cellular characteristics and components is continuously accumulating, questions on their actual

expression under normal and pathological conditions will frequently arise. For studying such questions, homogeneous cell populations retaining their original *in vivo* status may become so important that techniques and instruments required for their purification will be further improved.

ESSENTIAL GUIDES FOR ISOLATION/PURIFICATION OF DRUG METABOLITES

Metabolite Isolation and Identification

Following the administration of drugs to either animals or man, very few of the drugs are excreted

unchanged. The majority undergo biotransformations by interaction with a complex series of enzymes. This process, known as drug metabolism, is not restricted to drugs but occurs with all chemicals that are taken in by living systems, including food additives, pesticides, carcinogens, etc. These chemicals are termed exogenous compounds, as opposed to endogenous, or naturally present, compounds.

Metabolic studies have made, and continue to make, fundamental contributions to the drug

discovery process and also to the elucidation of mechanisms of both drug action and toxicity. During the early stages of drug development, an evaluation of the metabolic dispositional profile of a compound may yield valuable information and significantly contribute to the drug candidate selection procedure. In addition, drug metabolism has a central role in the safety evaluation of novel drug substances, and the regulatory authority guidelines for toxicity testing all make reference to metabolic and pharmacokinetic data.

The reactions of drug metabolism may be divided into two groups, the phase I or functionalization reactions and the phase II or conjugation reactions. The phase I reactions involve either the introduction or unmasking of a functional group, e.g. hydroxyl, carboxyl or amino group, within a molecule by the processes of oxidation, reduction or hydrolysis. The groups introduced generally result in an increase in the polarity, and therefore the aqueous solubility, of the metabolite compared with the parent compound. Depending on the reaction type, the change in physicochemical properties may be relatively minor, e.g. dealkylation of a tertiary to a secondary amine, or substantial, e.g. hydrolysis of an ester or amide.

The phase II reactions are biosynthetic and involve the addition of an endogenous molecule to the drug, or a phase I metabolite of the drug, by reaction with a suitable functional group, e.g. carboxyl, hydroxyl, amino, etc. The products of these reactions are generally polar, hydrophilic molecules that are ionized under physiological conditions, and hence the excretion of the foreign compound into urine or bile is facilitated. Examples of reaction types include conjugation with glucuronic acid, sulfate, glutathione and amino acids, all of which result in an increase in the polarity of the product compared to the drug. Some conjugation reactions, namely methylation and acetylation, may result in an increase in the lipid solubility of the metabolite compared that of the drug; however, this depends very much on the nature of the substrate. The two phases of drug metabolism are intimately linked, as shown in Figure 1.

As a result of the metabolic transformations outlined here, and analytical sample of biological origin may contain several substances which vary markedly in their physicochemical properties. For example metabolic products may be acidic, basic, neutral or zwitterionic and relatively hydrophilic or hydrophobic. The examination of such samples therefore presents the bioanalyst with a considerable challenge as the sample will contain relatively small quantities of structurally related materials dispersed in an extreme-

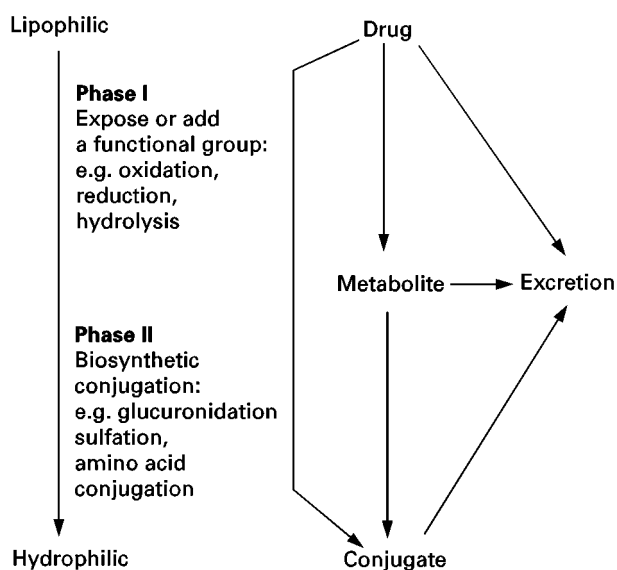

Figure 1 Relationships between phase I and phase II metabolic transformations.

ly complex matrix containing numerous potentially interfering endogenous materials. The isolation and characterization of metabolic products therefore requires a range of analytical methodologies, primarily in the areas of separation and spectroscopic techniques.

Sample Types

The range of techniques used to investigate the metabolism of drugs is relatively wide (Table 1) and the bioanalyst may therefore be presented with samples which vary markedly in terms of both their nature and origin. In *in vivo* metabolic studies, following the administration of a drug to either animals or humans, the major sample types examined include blood, plasma, urine, faeces and less commonly bile and milk. In *in vitro* methodology, sample types may

Table 1 Biological techniques used in drug metabolism

Methodology	Example
Administration of the drug to whole animals	Human or standard laboratory species, e.g. rat, dog, etc.
Isolated perfused organs	Liver, kidney, lung, intestine
Tissue slices	Liver, kidney
Isolated cells	Hepatocytes, renal cells, lung cells, enterocytes, blood cells
Subcellular fractions	Whole tissue homogenates, postmitochondrial supernatant, microsomal fractions, cytosol
Purified enzymes	Cytochrome P-450 and flavin monooxygenases

range from relatively clean perfusion fluids to complex tissue homogenates. Thus the bioanalyst may be presented with liquid, semisolid and solid samples for evaluation, each of which presents different problems. Plasma, for example, contains relatively high concentrations of proteins which may interfere with the chromatographic separation of metabolites or damage chromatographic stationary phases. The samples therefore require deproteination prior to analysis. Samples which are solids, or semisolids, may affect the separation characteristics of solid-phase extraction cartridges and it is frequently the case that such samples are homogenized prior to analysis.

Preliminary Sample Pretreatment

Because of the nature of the sample types and the potential range of physicochemical properties of the analytes, the samples encountered in metabolic studies generally require extensive pretreatment prior to instrumental analysis. It is essential that any manipulations carried out on the sample do not result in *ex vivo* changes to the analytes. A general approach to sample treatment is presented in Figure 2. Preliminary sample preparation plays an important role in the specificity of an analytical procedure. The initial step involves sample clean-up to remove potentially interfering substances, fractionation of the metabolic products according to their physicochemical properties, concentration of the sample for analysis and possible hydrolysis of conjugated metabolites. Having obtained a primary extract, the analytes are further purified, generally by a chromatographic procedure, prior to characterization by conventional spectroscopic techniques.

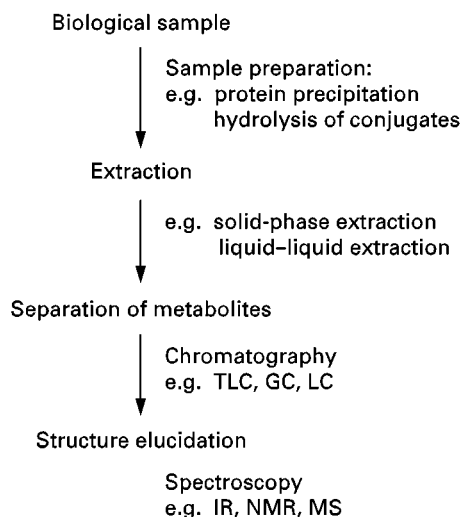

Figure 2 General approach for the isolation and characterization of metabolic products.

Hydrolysis of Conjugates

One of the most frequently encountered phase II pathways is conjugation with glucuronic acid. Several functionalities undergo this reaction, yielding a variety of bond types between the sugar moiety and the aglycone, e.g. carboxyl groups yield acyl glucuronides, phenolic and alcoholic hydroxyl groups yield ether linkages, thiols and amino functions yield S- and N-glucuronides respectively, and examples of carbon glucuronides are also known. The stability of these various linkages varies considerably, as does their susceptibility to hydrolytic treatments, the common methods of hydrolysis being mild alkali, acid or treatment with the enzyme β -glucuronidase.

A number of problems may occur during sample pretreatment; acyl glucuronides for example are relatively labile under mild alkaline conditions and may undergo hydrolysis in samples which are not stored with care. An additional problem with compounds of this type is that they also undergo facile intramolecular rearrangement at mild alkaline pH giving rise to mixtures of the corresponding 2-, 3- and 4-O-acyl esters of glucuronic acid. Such glucuronic acid esters are resistant to hydrolysis by β -glucuronidase but may be hydrolysed by treatment with mild alkali. Thus the amount of aglycone liberated by treatment of the conjugate with the enzyme may be lower than that found following treatment with alkali. Etheral glucuronides are stable to treatment with mild alkali, but may be hydrolysed with acid or β -glucuronidase. The stability of both N- and S-glucuronides to either chemical or enzymatic treatment is highly dependent on the nature of the aglycone and the bond type. Carbon-linked glucuronide conjugates are resistant to β -glucuronidase.

The liberation of an aglycone upon incubation of a conjugate with β -glucuronidase may only be taken as presumptive evidence that the conjugate is a glucuronide if adequate controls have been carried out, e.g. inhibition of hydrolysis by the specific β -glucuronidase inhibitor, saccharo-1,4-lactone, identification of the carbohydrate moiety by chromatography and detection with naphthoresorcinol.

Sulfation is a relatively common conjugation reaction for phenolic hydroxyls, alcohols and some amino compounds. Sulfate conjugates may be hydrolysed by aryl sulfatases. However, the commercially available preparations may be contaminated with β -glucuronidase, which should be inhibited by the addition of saccharo 1,4-lactone. Acid hydrolysis of solvolysis may also be employed but the reactivity of the conjugates may vary considerably.

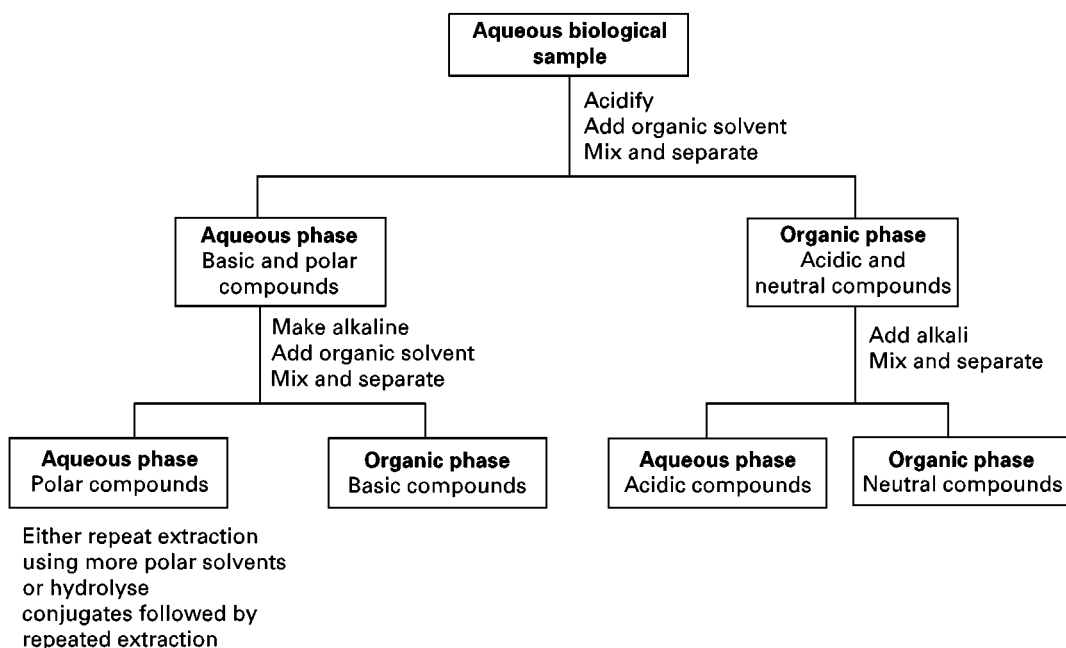

Figure 3 General scheme for the fractionation of drug metabolites using solvent extraction.

In contrast, amino acid conjugates of carboxylic acids are relatively stable and may be isolated and characterized by conventional methodology.

Methods of Isolation – Extraction Techniques

Extraction techniques may be used for the preliminary purification and fractionation of metabolic products from the biological matrix. Further purification of the individual metabolites may be achieved using chromatographic techniques.

Liquid–Liquid Extraction

As pointed out previously, drug metabolites vary greatly in terms of their physicochemical properties. Selective isolation of material may be achieved by extraction from the aqueous-based biological samples, after appropriate adjustment of pH, using an immiscible solvent. The choice of solvent is critical and it may be possible to fractionate the analytes by sequential extraction using solvents of different polarities, with or without adjustment of sample pH. Having obtained an organic extract of the compounds of interest the sample may be cleaned up further by ‘back-extraction’ into an aqueous phase with appropriate pH adjustment. A general scheme for the extraction of a drug and metabolites is presented in **Figure 3** and examples of commonly used solvents. Used either alone or in combination, are

presented in **Table 2**. Thus a particular drug or its metabolites can be selectively isolated from a biological matrix by a consideration of the physicochemical properties of the material, careful choice of solvent and adjustment of the pH of the aqueous medium. Ideally the solvent should completely extract the drug and its metabolites in a single extraction while keeping the amount of coextracted endogenous compounds to a minimum. However, the efficiency of the extraction procedure must be investigated and a double or triple extraction coupled with a ‘salting out’ procedure may be necessary.

Solvents for extraction should be of high purity grade and it is frequently important that they are distilled prior to use. This distillation will ensure that the solvents are free of trace quantities of solutes which on sample concentration may be present in

Table 2 Examples of commonly used solvents for extraction of biological fluids

<i>Solvent</i>	<i>Dielectric constant</i>	<i>Boiling point (°C)</i>
<i>n</i> -Hexane	1.9	68.7
<i>n</i> -Heptane	2.0	98.4
Carbon tetrachloride	2.2	76.8
Toluene	2.4	111.0
Diethyl ether	4.3	34.5
Chloroform	4.8	61.2
Ethyl acetate	6.0	77.1
Dichloromethane	9.1	40.2

concentrations greater than that of the analytes and may therefore interfere with the subsequent analysis. Phthalates for example are universal contaminants and are frequently observed in the mass spectra of metabolic products. Solvents such as diethyl ether frequently contain aldehydic impurities which may react with the analyte, e.g. (–)-ephedrine reacts with the acetaldehyde, propionaldehyde or formaldehyde present in ether to yield a series of oxazolidine derivatives during isolation. Chlorinated solvents should be used with caution in the presence of basic compounds; several analgesic agents, e.g. dextromethorphan, pethidine and methadone, have been shown to undergo alkylation during the concentration of dichloromethane extracts of the drugs. Traces of peroxides rapidly form in diethyl ether and may oxidize drugs, or their metabolites. The products of such reactions may then be erroneously identified as metabolites. Additional problems may also arise during concentration of extracts because of the degradation of thermolabile compounds and the loss of volatile compounds. Evaporation under reduced pressure and/or freeze-drying are useful alternative approaches.

Ion Pair Extraction

Highly polar metabolites cannot usually be extracted efficiently using solvents. In this case the metabolites, in their ionized state, can be paired with a counterion of opposite charge. Isolation of several biogenic amines, together with some of their metabolites, has been achieved by this approach. Catecholamines and their derivatives, for example, have been extracted from biological samples using di(2-ethylhexyl)phosphoric acid as a counterion.

Liquid–Solid Extraction

The isolation of drugs and their metabolites by adsorption methods offers an alternative approach to the traditional solvent extraction. Liquid–solid extraction, also known as solid-phase extraction (SPE) employs a wide range of materials including coated charcoal, silica, alumina and ion exchange resins. The biological fluid is passed through a column packed with the adsorbent and the materials of interest are separated from the components of the matrix by elution with an appropriate solvent. The success of the technique depends on the affinity of the analytes for the adsorbent and the strength of the eluting solvent.

In recent years the development of chemically bonded silica stationary phases for liquid chromatography (LC) has resulted in cartridge forms of these materials for liquid–solid extraction and SPE. The use

of these packings for extraction is based on the principles of LC; the packing materials however are of larger particle size (50 μm) than those used in LC. Thus analytes with a greater affinity for the stationary phase are retained and highly polar endogenous components of the matrix may be eluted with polar solvents. The retained materials may then be selectively eluted from the packing depending on their physicochemical properties, the nature of the adsorbent and the elution solvent. The range of phases for SPE is fairly extensive and includes C_2 , C_8 and C_{18} alkyl, phenyl, cyclohexyl, amino, diol and cyano, in addition to a variety of ion exchange phases. This range allows considerable versatility in terms of both selectivity and specificity for analyte isolation. SPE is superior in many respects to solvent extraction; it is highly reproducible, efficient and easier to automate, it generates less waste solvent and the only major drawback is the relatively high cost of the cartridges.

Methods of Isolation – Chromatographic Techniques

Chromatographic techniques are extensively used in bioanalysis for the separation, isolation and purification of drugs and their metabolites from biological fluids. Such techniques can provide useful preliminary information concerning the physicochemical properties of the metabolites in relation to those of the drug. Although they give little information concerning specific chemical structures, comparison of the chromatographic properties of an analyte with those of an authentic reference compound may provide sufficient information to establish the identity of a particular metabolic product.

Thin-Layer Chromatography

Thin-layer chromatography (TLC) is relatively cheap, easy to use, rapid and robust. These features account for the widespread use of the technique in metabolic studies, particularly for the isolation and purification of analytes prior to their characterization by spectroscopic techniques. A wide variety of stationary phases is available; these include silica gel, alumina and a number of bonded hydrocarbon phases (e.g. C_2 , C_8 , C_{18}) for reversed-phase and ion exchange separations. Such phases are coated onto plastic, aluminium foil or glass supports. A recent innovation in TLC stationary phase technology involves the introduction of high performance thin-layer chromatographic (HPTLC) plates which are coated with a layer (200 μm) of 5- μm particle size silica which offers improved performance in terms of resolution and

speed of chromatographic development. A number of chiral TLC phases have also been introduced. However the application of these phases in bioanalytical studies has been limited.

The chromatographic phases can be prepared with fluorescent indicators which facilitate the detection of ultraviolet absorbing analytes. The visualization of analytes may also be achieved by the use of a wide range of chromogenic spray reagents. The colour reactions observed with appropriate reagents may be of assistance in the determination of class of metabolite, e.g. glycine conjugates yield characteristic red-orange colours on treatment with *p*-dimethylaminobenzaldehyde, naphthoresorcinol is used for the detection of glucuronides, potassium dichromate–silver nitrate for sulphur(II) and ninhydrin for glutathione conjugates.

The main application of TLC in metabolic studies is in the isolation of metabolites, for subsequent identification by spectroscopic techniques. However, it can also be used quantitatively if radiolabelled drugs are used, or by the application of scanning densitometry.

Gas Chromatography

Gas chromatography (GC) is the technique of choice for the separation and determination of volatile, thermally stable and relatively low relative-molecular-mass drugs and metabolites. GC separation may be carried out using either packed or capillary columns. GC columns are usually made of glass, stainless-steel, copper, aluminium or PTFE (polytetrafluoroethylene). However in metabolic studies glass columns are preferred to minimize the potential thermal breakdown of metabolites during analysis. For example, the decomposition of primary and secondary hydroxylamines, formed on metabolic *N*-oxidation of the corresponding amines, takes place readily on the heated surfaces of metal columns.

A wide range of stationary phases is available for GC separation and a variety of solid support materials for packed columns is encountered. The amount of loading of the stationary phase on the support may also vary considerably, thus the number of possible combinations of phase and support are essentially unlimited. Liquid phases based on polymers of poly(ethylene glycol) and dimethylsilicone have been widely used in bioanalysis. The poly(ethylene glycols) are polar and Carbowax 20M is frequently used, both with and without potassium hydroxide, as a stationary phase. Carbowax 20M is a particularly useful phase for analysis of low relative-molecular-mass amines and their metabolites, e.g. amphetamine and related compounds. Problems arise with compounds of greater molecular mass because of the maximum

operating temperature of 200°C for Carbowax 20M. In contrast the silicon phases may be used up to c. 350°C, and common phases encountered in metabolic studies include OV1 and OV101 polymers and the more polar phenylmethylsilicones OV17 and OV25. The most commonly used support materials in bioanalysis include Chromosorb G and W, Gas Chrom Q, Haloport F and Chromosorb 750. These support materials are not entirely inert and are frequently washed with acid or silanized prior to being coated with the stationary phase. Glass beads may also be used as support material for GC because of their inert nature and they may also be coated with low loadings of stationary phase. *N*-Hydroxyamphetamine, a thermolabile metabolite of amphetamine, was first chromatographed successfully without prior derivatization using a column containing Carbowax 20M (0.2%) coated onto a glass bead support.

Several GC detector systems have been described. However only four types are commonly used in bioanalysis, the flame ionization detector, the electron capture detector, the nitrogen–phosphorus detector, and the mass spectrometer. Of these the mass spectrometer is the most specific and can provide information on the structural features of compounds. The flame ionization detector is the most widely used in metabolic studies, and sample quantities as low as 1 ng can be determined depending on detector design. Electron capture detectors respond to halogenated compounds, and compounds containing nitro groups or conjugated carbonyls, etc., and thus the suitability of this detector for metabolic studies depends on the structure of the analyte. This selectivity, together with sensitivity (detection of 1 pg of material is possible) increases the utility of this system. Derivatization of compounds that do not contain halogens with appropriate reagents frequently yields volatile products which are ideal for analysis by GC using this detector system, e.g. the analysis of debrisoquine and its 4-hydroxy metabolite following derivatization with hexafluoroacetylacetone to yield the corresponding bis(trifluoromethyl)pyrimidine derivatives. Nitrogen–phosphorus detectors are extremely sensitive and are 20 000–40 000 times more sensitive to nitrogen than to carbon. In bioanalysis such detectors are useful particularly for heterocyclic compounds, which are less likely to lose nitrogen via metabolic deamination than are acyclic compounds.

The products of metabolism are generally more polar than the drug, have less volatility, long GC retention times and produce tailing peaks. Thus metabolites are frequently derivatized prior to analysis to increase volatility, modify chromatographic properties and increase detector response. The most common techniques are: silylation, the replacement

of active hydrogen by trimethylsilyl groups (e.g. OH, SH, NH₂); alkylation using diazomethane, dimethylformamide, dialkyl acetals, or boron trifluoride and an alcohol; and acylation using perfluoroacyl reagents to yield trifluoroacetyl, heptafluorobutyl, etc. derivatives.

Liquid Chromatography

LC is an extremely versatile technique and has a number of advantages over GC in terms of bioanalysis. For example, highly polar compounds which are difficult to extract from aqueous solutions, e.g. glucuronide and sulfate conjugates and quaternary ammonium derivatives, may be analysed directly without the necessity for extraction; the technique is normally carried out at room temperature and therefore thermolability of analytes is not a major consideration; and the technique is nondestructive so that the eluent containing the analytes may be collected and used for additional offline characterization.

A variety of different stationary phases is available for LC, but the reversed-phase packings (e.g. C₂, C₈, C₁₈, phenyl) are the most commonly used in metabolic studies. The mobile phases utilized with such columns are based on aqueous solvents containing variable quantities of organic modifiers. Such systems allow analyte sample preparation to be simplified, reducing the preanalysis manipulation steps. Provided the chromatographic system has sufficient resolving power, it may be possible to inject directly either a dilute sample or a plasma sample following precipitation of plasma proteins with an organic solvent compatible with the LC mobile phase. This approach has the obvious advantages of reduction of tedious sample manipulation steps and also in the reduction of human exposure to samples of clinical origin. A disadvantage of the direct injection approach is that protein precipitation may occur on injection of plasma samples into the chromatograph. However, the use of precolumns can protect the analytical column and the instrument.

The most frequently used detection systems in LC analysis are either fixed- or variable-wavelength ultraviolet (UV) detectors, fluorescence detectors or electrochemical detectors. While analyte derivatization is not as commonly used with LC, as with GC, derivatives may be used to enhance the detector sensitivity, particularly if fluorescence is used. Multiple-wavelength UV detectors and the diode array detector are particularly useful in metabolic studies. The use of such detectors in analysis provides a three-dimensional chromatographic retention and the entire spectrum of a sample may be determined in a single chromatographic run. The main applications of these

detector systems in bioanalysis are to ensure chromatographic peak purity and to provide initial spectroscopic data for metabolite identification. If the compound under investigation is radiolabelled then a suitable LC radiodetector may also be used to facilitate the detection of metabolites.

Capillary Electrophoresis

A technique that is likely to make an impact on bioanalysis in the near future is capillary electrophoresis (CE). This technique, and its variants, offers a number of advantages over conventional chromatographic techniques, e.g. high column efficiencies and short analysis times, particularly where samples are complex mixtures. At present CE instruments are limited in terms of sample size, but this may be an advantage when working with biological fluids as it minimizes potential contaminants. An additional advantage of the technique is that by manipulation of the analytical conditions the nature of the components entering the capillary may be controlled and interference effects reduced. A variety of detector systems has been described for CE, including fluorescence, electrochemical and mass spectrometry systems, but the majority of commercially available instruments incorporate a sensitive UV detector system. Bioanalytical applications of CE have been described for the determination of cefpiramide and anticancer agents in human plasma.

Methods of Identification

The elucidation of metabolite structure is dependent on the use of spectroscopic techniques, either directly linked to chromatographic systems (the so-called 'hyphenated': techniques, GC-MS, LC-MS), or used offline following the isolation and purification of analytes. The main techniques used in bioanalysis are ultraviolet (UV), infrared (IR) and nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS). However, the technique or combination of techniques finally adopted will be dependent on the complexity of the problem and the amount of pure isolated material available.

Ultraviolet Spectroscopy

This technique is widely used for the quantitative analysis of drugs and metabolites in biological samples. However, the amount of structural information which can be obtained from a UV spectrum of a metabolite is limited. If the site of metabolism in a molecule is at, or adjacent to, a chromophore then the UV spectrum is likely to yield useful structural information, e.g. oxidation of an aromatic ring to

yield a phenol, the spectrum of which can be influenced by alteration of pH, reduction of an aromatic nitro group to yield an amine, and reactions which result in the introduction of conjugated double bonds, e.g. aromatization.

Infrared Spectroscopy

IR spectra are highly diagnostic and the examination of an IR spectrum provides a simple, rapid and often reliable method of assigning metabolite structure. Until relatively recently the sensitivity of IR spectrometers restricted their application in metabolic studies but the development of Fourier transform infrared (FTIR) and the application of these instruments as detector systems for both GC and supercritical fluid chromatography has increased the potential of the technique in bioanalysis significantly.

Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy has been routinely used in metabolic studies as a means of structure elucidation for a number of years. The major limitation of the technique has been sensitivity. However instrumental developments, with improvements in resolution, analytical power and sensitivity, have changed the way the technique is used in bioanalysis.

There are now a number of reports of direct NMR examination of biological samples with minimal or no preliminary sample clean-up processes and biological fluids have been placed directly in the NMR sample tube. It has also been possible, using NMR techniques, to examine metabolism and distribution in cells and organs.

Proton NMR is the most widely used technique in drug metabolism because of its high sensitivity and the large number of observable protons in most drugs and their metabolites. As bioanalytical samples are initially obtained in aqueous solution the intense water signal present must be either eliminated, suppressed or edited out of the spectrum. Signals from endogenous materials may also obscure signals of interest because of overlap resulting from the narrow chemical shift range in proton NMR. Direct proton NMR has been used to examine the urinary disposition of paracetamol following the oral administration of the drug to humans. Using this approach it was possible to examine the urinary metabolite profile following both therapeutic doses and overdoses of the drug.

Other nuclei of interest in bioanalysis include ^{19}F , ^{31}P , ^{15}N and ^{13}C , although sensitivity may be a problem with some of these nuclei (e.g. ^{15}N). An approach which may yield useful information with these nuclei is to use compounds appropriately labelled with

stable isotopes. This approach may be particularly useful if the label is introduced at a site which undergoes transformation. For example the fate of [carboxyl- ^{13}C]phenylacetic acid has been examined following administration to a horse. This compound undergoes both amino acid and glucuronic acid conjugation and the major metabolites could readily be distinguished following direct NMR examination of urine samples and observation of the ^{13}C -carbonyl resonances. NMR has also been used directly linked with HPLC for metabolite work.

Mass Spectrometry

As a result of its extreme sensitivity and ability to provide diagnostic information, MS is the standard technique for the identification of metabolic products. All the major MS techniques have been utilized in metabolic investigations and thus it is relatively easy to find publications detailing applications of electron impact, chemical ionization, field desorption and fast atom bombardment in drug metabolism. The major advantage of MS is the ability to use the technique in combination with either GC or LC. Such hyphenated techniques, particularly GC-MS, have been extensively used in metabolic studies and the development of thermospray ionization for LC-MS has enabled spectra of nonvolatile hydrophilic analytes, e.g. metabolic conjugates, to be determined directly. As a result of the variety of ionization modes available, and the ability to link the technique to GC or LC, there are few bioanalytical problems to which MS cannot make a valuable contribution.

There are essentially three main applications of MS, particularly the hyphenated techniques, in metabolic studies.

1. The characterization and structure elucidation of metabolic products.
2. Quantitative analysis using the mass spectrometer as a sensitive chromatographic detector for selected single or multiple ion monitoring, using for example compounds labelled with stable isotopes as internal standards. An alternative approach involves the administration of a labelled compound to a patient who is at steady state, and use of the nonlabelled material to examine the pharmacokinetics of what is effectively a 'single' drug dose under these conditions.
3. Mechanistic investigations, e.g. the source of oxygen in a metabolite may be determined by carrying out appropriate experiments using $^{18}\text{O}_2$ or H_2^{18}O ; the use of compounds labelled with stable isotopes, e.g. replacement of hydrogen with deuterium to determine kinetic isotope effects on metabolism.

MS has made a number of important contributions to drug metabolism and the further development of the technique, together with advances in instrumentation, will enhance its application in this area.

ESSENTIAL GUIDES FOR ISOLATION/PURIFICATION OF ENZYMES AND PROTEINS

S. Doonan, University of East London, UK

Copyright © 2000 Academic Press

Nature of the Problem

The purification of proteins presents a unique challenge in the field of separation science. Typically, the particular protein to be isolated will constitute 1% or less (sometimes much less) of the material in the original extract and all of the contaminants will have basically the same chemical characteristics, i.e. they are all proteins. There is the added complication that for most purposes it is necessary to retain the biological activity of the protein, and the inherent instability of protein structures restricts the range of temperatures and solvent compositions that can be used during purification.

Tools for its Solution

Clearly, methods for the separation of proteins must be based on those characteristics in which they differ from one another. The most important of these are listed in Table 1 along with the separation techniques that exploit those differences. These various properties are not of equal generality or of equal utility for purification purposes.

By far the most widely used technique for protein isolation is ion exchange chromatography. The generality of the method arises from the fact that proteins contain ionizable amino acids and hence carry a net

charge at all pH values except the unique pH (the isoelectric point) at which the positive and negative charges are equal. Moreover, two proteins that have the same charge at a particular pH are likely to differ in charge at some other pH. Ion exchange chromatography is technically simple and can be adopted for use over a very large range of scales. Chromatofocusing and isoelectric focusing are methods that depend on the differences in isoelectric points between proteins but are less widely used for preparative work than is ion exchange chromatography because of increased cost, restrictions of scale and technical difficulty.

Electrophoresis is a special case. Electrophoretic methods are of central importance in analytical protein chemistry but, until recently, have not proved

Table 1 Properties of proteins that can be exploited for purification and associated experimental methods

Electrical charge	Ion exchange chromatography Chromatofocusing Isoelectric focusing (Electrophoresis)
Hydrophobic surface regions	Hydrophobic chromatography
General surface properties	Salt fractionation
Size	Size-exclusion chromatography Membrane filtration
Specific binding site	Affinity chromatography Dye-binding chromatography Lectin chromatography
Surface carbohydrate	Metal chelate chromatography
Metal-binding site	Immunoaffinity chromatography
Antigenic determinants	

useful for purification purposes. The reason for the change has been the development of ultra high sensitivity techniques for structural analysis that has blurred the distinction between analytical and preparative methods. Hence the inclusion of electrophoresis in Table 1 as a preparative method, although it serves that purpose for a limited range of applications (see later).

Although the surfaces of most soluble proteins are predominantly polar, many of them have patches of hydrophobic amino acids that, under appropriate conditions (usually at high salt concentrations), can bind to hydrophobic matrices. This provides a method for separation provided that elution from the matrix can be achieved under conditions that do not lead to loss of biological activity.

Proteins differ from one another in their solubilities in salt solutions. Clearly, in a complex mixture of proteins the solubilities of the components will overlap and hence fractional precipitation with salt, usually ammonium sulfate, provides only a crude separation method. However, it is widely used as a first step in purification procedures, particularly when working on a large scale. Occasionally, fractional precipitation with an organic solvent (ethanol, acetone) is used but there is a possibility of protein denaturation at high solvent concentrations.

Proteins also differ from one another in size and this can be exploited in size-exclusion chromatography. This is inherently a method of low resolution and can rarely achieve more than separation of mixtures of proteins into broad size classes. However, a very important application of size-exclusion chromatography is for changing the composition (e.g. the pH) of the solvent between steps in a purification procedure. Dialysis can also be used for this purpose but is much slower. The same restriction of low resolution applies to separations using membrane filtration, but this technique is of enormous utility at various stages in a purification schedule for reducing the volume of protein solutions: the single major 'contaminant' in a protein solution is water.

Whereas the methods above depend on differences in structures of proteins there is also a set of procedures that depend essentially on differences in biological activity. In the vast majority of cases, biological activity of a protein depends on it recognizing and binding to a ligand. For example, enzymes bind to substrates and inhibitors, hormones bind to receptors, antibodies bind to antigens and so on. This specific biological activity can be exploited by construction of a matrix to which the appropriate ligand is (usually covalently) attached. Passage of a protein mixture through the resulting affinity matrix should result in binding of one or a small number of

proteins that recognize the ligand. Subsequent elution can be achieved by passage of a solution of the ligand, or a suitable analogue, through the column. This method has seen widespread application in the purification of enzymes and is in principle capable of very high selectivity because of the specificity of enzyme/substrate or enzyme/inhibitor binding. The selectivity achieved is, however, often limited by the fact that the ligand may be charged and hence gives rise to ion exchange effects, or it may be hydrophobic and give rise to nonspecific hydrophobic interactions. Despite this, affinity chromatography is a very powerful method and its use is restricted more by the fact that it is often necessary to design and synthesize the affinity matrix oneself rather than by inherent limitations.

Dye binding chromatography is a variant of affinity chromatography and relies on the fact that a variety of chlorotriazine textile dyes interact moderately specifically with enzymes that have nucleotide (ATP, NAD(H), coenzyme A (CoA)) binding sites. The ability of dye-containing matrices to recognize nucleotide-dependent enzymes is not a purely affinity effect – indeed the structural similarity between the dyes used and the cofactors is not obvious – and includes elements of ion exchange and hydrophobic effects. Nevertheless, these methods often work remarkably well for isolation of groups of nucleotide-dependent enzymes or even of individual members when biospecific elution methods are used.

Lectin chromatography and metal chelate chromatography are available when the protein of interest has either surface carbohydrate or a metal-binding site, respectively. The former method depends on the fact that various plants produce proteins (lectins) that bind specifically to particular classes of carbohydrate. If the lectin is coupled to an appropriate support then the product matrix will specifically bind glycoproteins from a mixture of proteins. Elution can be effected by passage of a solution of the appropriate monosaccharide through the column. In metal chelate chromatography the matrix has a chelating agent covalently attached and loaded with an appropriate metal ion. On passage of a mixture of proteins through the column those with a binding site for the metal will be retained and subsequently can be eluted by passage of a solution of metal ions through the column.

Immunoaffinity chromatography is in principle the most specific method available for protein isolation. It involves raising an antibody to the target protein, attaching the antibody to a supporting material and then using this as an affinity matrix. The extreme specificity of antigen-antibody interactions should ensure high selectivity in binding the

target protein. However, there are two problems. Clearly, the protein has to have been isolated previously in order for an antibody to be produced. A highly purified protein will be required to raise polyclonal antibodies. Alternatively, a partly purified antigen can be used to produce monoclonal antibodies but this adds an extensive new dimension to a purification procedure. The major restriction on the application of the method, however, is the difficulty of elution of proteins from the immunoaffinity matrix once bound. The tightness of binding often requires extreme conditions for efficient elution (very high or low pH, presence of chaotropic agents) such that many protein molecules become denatured during the elution process.

Putting them Together

Faced with the variety of methods available for the separation of proteins the question arises as to which of them to use and in which order for development of a purification schedule for a particular protein. The answer to this depends on a whole host of issues such as:

- how much protein is required?
- what sources of the protein are available?
- has the gene for the protein been cloned?
- is the protein required to be completely pure?
- is it necessary to retain biological activity?
- has it been done before?

If the answer to the last question is positive, the obvious approach is to try to reproduce the reported purification procedure. It may not work exactly as described – small variations in procedures between laboratories can give rise to significant differences in the behaviour of proteins during purification – but it should be relatively easy to adjust conditions to get it right. Development of a new protocol is time-consuming and not usually worthwhile unless it is to be used repeatedly and an existing method appears to be unnecessarily cumbersome; even then the published method should provide a valuable guide on how to make improvements.

What follows are descriptions of the sorts of schedules of methods that might be used in a variety of situations.

Large-Scale Isolation of an Active Protein

Large-scale here is taken to mean a laboratory-scale purification of a few tens of milligrams of protein. Industrial scale purification might well follow the same general pattern but there would be engineering problems associated with scaling up that will not be dealt with here. In the case of a protein to

Figure 1 Flow chart for the purification of an enzyme.

be used for therapeutic purposes there would also be specific requirements imposed by regulatory agencies that are beyond the scope of the present discussion.

The flow chart in **Figure 1** outlines steps in the protocol for purification of an enzyme developed in the author's laboratory. The starting material was 5 kg of pig liver. If the source of the enzyme or other protein is not of importance for the purpose of the investigation then the best choice is to use an animal tissue that can be obtained in quantity from a commercial abattoir. Animal tissues are generally easy to homogenize in a domestic food blender. Other sources such as fungi, bacteria and plants present difficulties in disruption of the tissue and are best avoided unless the source is constrained by the problem in hand.

Ten litres of buffer was used for homogenization and, after removal of debris, the volume of protein solution was 8.5 L. This volume of solution is difficult to handle and hence fractional precipitation with ammonium sulfate was used both to obtain an initial crude purification and, more importantly,

reduce the volume. After centrifugation of the active fraction, resuspension of the pellet and dialysis the volume was reduced to 500 mL.

The next step was ion exchange chromatography. There were choices to be made of whether to use a cation or anion exchanger, and as to which of the various available supporting materials (cellulose, Sepharose, Superose) was to be preferred. In the present case, a cellulose-based matrix was chosen. This was essentially because the amount of protein in the sample (about 100 g) made it necessary to use a large amount of exchanger and correspondingly a large column. Cellulose-based exchangers are much cheaper than other varieties and, in addition, large columns of cellulose exchangers have better flow characteristics than do those of other materials. The choice of carboxymethyl (CM) cellulose rather than the anion exchanger diethylaminoethyl (DEAE) cellulose was dictated by previous experience of the behaviour of the two materials for the separation of crude protein mixtures.

The protein of interest was retained by the CM-cellulose and was eluted by application of a gradient of increasing sodium chloride. This is to be preferred over the other possibility of using conditions where the protein is not retained on the column since a higher degree of purification is likely to be achieved on gradient elution. After combination and concentration of the active fractions the volume of the sample had been reduced to about 50 mL and the amount of protein to about 1 g. These amounts were suitable for the application of a variety of small-scale but more highly resolving techniques. For example, had the enzyme of interest been a glycoprotein then lectin affinity chromatography would have been a good choice. Similarly, hydrophobic chromatography could have been used. An advantage of using the latter technique would have been that it would not have been necessary to remove the sodium chloride from the sample after gradient elution from CM-cellulose given that in hydrophobic chromatography the sample is applied in a solution of high salt content to promote interaction with the matrix.

In practise it was relatively easy in the present case to develop an affinity matrix for the enzyme based on an analogue of the substrate. It was worthwhile to do this because it was intended to repeat the purification frequently so that the time involved in preparing the affinity matrix was subsequently recovered. If a purification is essentially one-off then this is unlikely to be the case.

After affinity chromatography the product was examined by electrophoresis and found to contain

two minor contaminants, both more basic than the target enzyme. Hence, a final step using an anion exchanger under conditions where the protein of interest was absorbed but the contaminants were not, or were bound more weakly, suggested itself. The exchanger chosen was DEAE-Sepharose, which has a greater resolving power than cellulose-based products.

The final product of the purification procedure was 28 mg of protein that was homogeneous, as judged by the usual criterion of producing a single band after sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). The enzyme had been purified 6000-fold compared with the original homogenate and the yield was about 50%.

Small-Scale Isolation of an Active Protein

Isolation of a few milligrams of active protein follows the same general principles as outlined above but can often be achieved in a smaller number of steps. For example it is not necessary to carry out fractional precipitation with salt because the small volume of protein solution will allow direct use of ion exchange chromatography as the first purification step. In addition, because of the small scale of the procedure, the high resolving power of ion exchange chromatography or of hydrophobic chromatography in fast protein liquid chromatography (FPLC) mode can be exploited, which may allow a reduction in the number of chromatographic steps required. FPLC differs from conventional column chromatography in that it employs very fine particle size matrices that offer greater resolving power for protein mixtures. Fully automated equipment is also available that allows for greater reproducibility between runs than do conventional methods. Capacity is, however, limited.

Proteins from Sub-Cellular Organelles

Many proteins in higher organisms exist in discrete subcellular organelles such as mitochondria, chloroplasts and lysosomes. If the target protein is one of these it may be advantageous to make a preparation of the organelle and isolate the protein from that rather than from a total tissue homogenate. Isolation of subcellular organelles is usually carried out by preparative differential centrifugation. Proteins can subsequently be extracted from the organelles and purified by standard techniques.

The advantage of this approach is obvious. Given that the organelles contain a more restricted range of proteins than does the parent cell then the purification procedure is likely to be much simpler. The downside is that the isolation of subcellular structures is time-consuming and, except on a relatively small

scale, there may not be a net saving of time in adopting this approach.

Membrane Proteins

Integral membrane proteins present special problems because of their location within membranes and because they are not soluble in aqueous buffer solutions. The first step will be to obtain a preparation of the membrane of interest, usually by differential centrifugation. Next, the protein has to be extracted from the membrane preparation, most commonly by using solutions of detergents such as Triton X-100, Lubrol PX, digitonin, sodium cholate, etc. This is a crucial step and the best detergent to use to obtain optimum release of the protein from the membrane fragments can be determined only by trial and error.

Once a soluble extract of the protein has been obtained its purification can be achieved using the usual chromatographic techniques except that, because of solubility problems, it will be necessary to maintain a standing concentration of detergent in the buffers. This frequently adversely affects the performance of ion exchange materials and more success in isolation of membrane proteins has been achieved by exploiting their binding properties, that is, by using various forms of affinity chromatography.

A final problem, once the protein has been purified, will usually be to remove the detergent from the preparation or to change the detergent type. This can be achieved by a variety of methods, including equilibrium dialysis, gel filtration and a variety of chromatographic methods.

Peripheral membrane proteins, that is, those that are only loosely associated with the membrane, do not usually present special problems. They can be released from membrane preparations by salt extraction or by changes in pH, are usually soluble in aqueous buffers, and are amenable to the usual purification methods.

Products from Cloned Genes

As a result of the rapid developments in genetic technology in recent years it is now relatively easy to clone the gene for any protein of interest and express it in a suitable bacterial host. This does not change the methods that are available for purification but it does allow for simplification of the purification procedure. An obvious example is that expression of the gene can be manipulated so that its protein product represents a very high percentage of the protein in the host cell. Values of up to 50% have been achieved, which obviously simplifies the subsequent purification. Similarly, some success has

been achieved in modifying genes by the attachment of an export signal so that the host organism excretes the protein product into the culture medium.

Other approaches to facilitating purification of cloned gene products involve the construction of fusion proteins. One example of this is where a tail of basic residues (lysine or arginine) is engineered onto the protein. This tail will make the protein very basic and hence increase its affinity for ion exchangers such as CM-Sephadex. If, after elution from the exchanger, further purification is required then the tail can be removed (by digestion with carboxypeptidase B) followed by further chromatography under the same conditions. The decreased basicity consequent on removal of the tail will ensure that the protein now behaves differently compared with any contaminants whose properties will not have been modified.

Other approaches involve engineering affinity labels onto the protein. For example, fusion products between a target protein and maltose-binding protein from *Escherichia coli* can be very readily purified by amylose affinity chromatography. Similarly, antibodies to certain small peptide sequences, referred to as flags, have been raised so that fusion proteins bearing these flag sequences can be readily purified by immunoaffinity chromatography.

Obviously, in any particular case the question needs to be asked as to whether the time and cost involved in genetic engineering of the desired protein product is justified in terms of the time saved in subsequent purification. The answer is likely to be positive only if the purification is to be repeated frequently.

Special Cases

The procedures described above should be used when it is important to retain the biological activity of the protein of interest. Essentially, this means using experimental conditions under which the native three-dimensional structure of the protein is preserved. There are some situations where this is not necessary and all that is important is that the primary structure of the protein remains unchanged. An important example of this is where the protein is required for amino acid sequence analysis. In this case additional techniques can be used for purification. For example reverse-phase HPLC using hydrocarbon (C_4 – C_{18}) stationary phases provides for high-resolution separation of proteins but elution often requires the use of organic solvents such as acetonitrile, which frequently leads to denaturation. The method is, however, extremely powerful for final

separation of partly purified proteins for sequence analysis.

For a variety of applications, including *N*-terminal sequence analysis using modern high-sensitivity techniques, only very small amounts of protein (a few micrograms) are required. For these applications the resolving power of SDS-PAGE can be exploited to separate even relatively crude mixtures. The protein of interest is then removed from the acrylamide gel, for example by using an appropriate blotting technique, and the blot subjected to analysis.

More recently this approach has been extended to the identification of proteins in cell homogenates. The total cell extract is separated by two-dimensional electrophoresis, most commonly using isoelectric focusing in the first dimension and SDS-PAGE in the second dimension. Individual spots are excised from the gel, the protein subjected to digestion with trypsin, and the trypsin fragments analysed by mass spectrometry. The set of peptide masses obtained is then scanned against a data bank of the masses of tryptic peptides from all known proteins. In most cases this allows unique identification of the protein in the gel spot, provided that its sequence is known either from direct analysis or by translation of a DNA sequence.

Detection and Quantification

It is clearly of central importance in any purification procedure that a method is available for detecting the presence of the protein of interest in the fractions from the various separation steps. In the case of enzymes this is easy because they possess catalytic activity that can be measured by some appropriate analytical technique. Other proteins might require the use of a bioassay, or an immunoassay, or perhaps the identification of the protein as a particular band produced on analytical electrophoresis.

What might not be so obvious is the importance of quantification of the recovery of the protein at each stage of the purification procedure – that is, of keeping an inventory. Unless this is done it is very easy to end up with a disappearing yield of the protein of interest and not to know at which step or steps it disappeared. At each step it is important to measure the total protein content and the amount of the

protein of interest. This allows not only the recovery but also the degree of enrichment of the protein to be determined. Any step for which either of these is low should be abandoned.

In the case of enzymes, keeping this inventory is straightforward; it is simply necessary to measure the catalytic activity of a known volume of the fractions. In other cases it is much more difficult. Bioassays can be very time consuming. Immunoassays are not usually too difficult, but in this case it is necessary to bear in mind that immunological reactivity of a protein may be retained even though biological activity has been lost. In the case of a protein with no known biological activity, or where the activity is very difficult to measure, then recovery can be assessed from the measurements of the intensity of the appropriate band produced by analytical electrophoresis. Whatever the difficulties, however, keeping a score card is essential if a successful purification protocol is to be developed.

ESSENTIAL GUIDES FOR ISOLATION/PURIFICATION OF IMMUNOGLOBULINS

A. Layer, P. Schneider, J.-D. Tissot and M. A. Duchosal, Service Régional Vaudois de Transfusion Sanguine, Lausanne, Switzerland

Copyright © 2000 Academic Press

Introduction

The immunoglobulins (Igs), proteins produced by B lymphocytes, have been extensively studied both at molecular and genetic levels. They consist of two identical heavy chains and two identical light chains having therefore the same isotype and the same type, respectively. Igs are purified for three main purposes. (i) as therapeutic injections to patients; (ii) for use as a tool in research or clinical diagnosis; and (iii) for their biochemical analysis (specificity, isotype or clonal diversity). Most of these applications require that the binding activity of Igs be retained throughout all the purification procedures.

Purification of Igs can be performed according to their physicochemical properties, their biological activities or a combination of both. The technique used will depend on the desired degree of purity and the amount and nature of the starting material. The methods that have been described are generally directly applicable to crude materials such as serum, ascitic fluid or cell culture supernatant. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) affords an efficient way of evaluating the degree of purity reached in affinity purifications. Several aspects of 2D-PAGE analysis are described in detail in two other articles 'Electrophoresis/Two-dimensional PAGE' and 'Clinical Applications of Electrophoresis/Electrophoresis' in this Encyclopedia.

As a general rule, and independently of the technique used, the starting material should always be devoid of any insoluble substances and the purification be preceded by centrifugation or filtration. Viscous fluids, such as serum, may be diluted before use, especially for chromatographic procedures. The solutions should contain a bacteriostatic agent, such as 0.02% sodium azide (NaN_3), and be kept on ice. Ig solutions should be handled gently, avoiding bubbling or frothing, because such manipulations may be

accompanied by denaturing effects, and may lead to protein precipitation.

Purification by Precipitation

Solubility of the proteins, particularly Igs, in water relies mainly on the ability to make hydrogen bonds between polar or ionic groups with water molecules (hydrophilic interactions), and on the capacity to maintain hydrophobic groups that cannot interact with water molecules buried inside the proteins. In addition, the solubility of Igs is temperature-dependent. Any external factor capable of modifying hydrogen bonds or decreasing the medium hydrophilicity will decrease the solubility of the proteins and may eventually lead to their precipitation. Each protein has its own physicochemical characteristic, including solubility. For this reason, several differential precipitation procedures can be developed to isolate Igs from various fluids. These procedures are presented below.

Differential Ethanol Precipitation

The first fractionation of plasma proteins for therapeutic use was described in 1949 by E.J. Cohn. The basic procedure, with few modifications, is still widely used in industrial fractionation centres. Basically, ethanol is added progressively to the medium to a final concentration varying from 8 to 40%. Subsequently, the temperature is decreased to -3°C and then to -5°C . Finally, the pH is decreased from 7.3 to 4.8. These steps yield precipitation fractions, called Cohn's fractions I-V. Fraction II contains the γ -globulins or Igs. The treatment of this fraction with caprylic acid (see below) allows the preparation of Igs that are enriched in IgA and IgM. This approach is used when large amounts of Igs are needed, i.e. for therapeutic purposes (from up to 5000 L plasma) and will not be detailed further.

Ammonium Sulfate Precipitation

Small and highly charged ions, such as ammonium ions, replace bound water molecules when present at a sufficient concentration. This decreases protein

solubility and, when the ammonium sulfate concentration is increased stepwise, a sequential precipitation of proteins may be obtained.

Practically, a saturated solution of ammonium sulfate (761 g L^{-1} ; 4.1 mol L^{-1}) is slowly added to a stirred (in order to avoid local over-increase in concentration) solution of Igs, until the final desired concentration, usually expressed as a percentage of ammonium sulfate saturation, is reached. Although some interspecies variability is observed for Ig solubility, a 50% ammonium sulfate saturation is usually appropriate for most Ig precipitation procedures. Pre-precipitation at 40% ammonium sulfate saturation may be useful to remove large protein aggregates and proteins that may precipitate at low ammonium ion concentration. The precipitation is allowed to occur at 4°C for 6–12 h. The precipitate is recovered by centrifugation at 2000–5000 g for 20–30 min. In general, the pellet is then gently solubilized in a minimal volume of a physiological buffer, and dialysed to remove the residual ammonium sulfate. Alternatively, Ig purity can be increased by washing the pellet with a 50% saturated solution and solubilization in PBS, followed by another round of ammonium sulfate Ig precipitation. When starting with serum or cell supernatant containing serum, this method allows the removal of most albumin and haemoglobin, but the precipitated fraction still contains several serum proteins in addition to Igs. In this case this approach must be coupled with another purification technique if pure material is needed. When starting with a serum-free cell culture supernatant, this method is convenient to isolate, and to concentrate, monoclonal Igs in one step. In addition, the method is easy, cheap and can be applied to large volumes.

Caprylic Acid Precipitation

The solubility of proteins is altered by the presence of some short chain fatty acids, such as octanoic acid (caprylic acid) at mildly acidic pH. Basically, caprylic acid increases medium hydrophobicity. In practice the pH of the starting solution must be adjusted to 4 by the addition of about 2 vol of a 60 mmol L^{-1} sodium acetate buffer. Then, 0.04–0.07 vol of caprylic acid (depending on the starting material as well as on the animal species of the Igs) is added drop by drop while stirring, and the solution is incubated at room temperature for 30 min. Under these conditions, most of the serum proteins are precipitated, with the exception of IgG, which is recovered in the supernatant after centrifugation at 5000 g for 10 min. This method bears similarities with that of ammonium sulfate precipitation. In particular, it needs to be coupled with another one to yield highly purified Ig fractions.

Chromatographic Methods

In chromatographic procedures, compounds in solution are separated by allowing them to flow through a selective medium poured in a column. Differential interactions between molecules and matrix are responsible for them migrating at various speeds, or even completely immobilizing them. Separated molecules are recovered in the effluent of the column. Several commercially available preparations allow separation of proteins according to their various physicochemical properties. Detailed information about the use of such media is furnished by the manufacturers or can be found in the literature for particular applications.

Ion Exchange Chromatography

An ion exchanger consists of a positively or negatively charged group covalently bound to an insoluble matrix. Charged molecules with complementary polarity to that of the immobilized groups bind to the matrix through electrostatic interactions, whereas uncharged or similarly charged molecules pass freely through the matrix. Since the net charge of a protein depends on the pH, the starting experimental conditions must be carefully chosen. The bound proteins may be desorbed either by change in pH, or by change in the ionic strength. The former modifies the charge of the protein, whereas salts compete with the binding of the protein to the resin. Addition of NaCl is most frequently used for elution. As the strength of the protein–matrix interaction depends on the net protein charge, a sequential elution can be performed by gradually increasing salt concentration. Because Igs have a more basic isoelectric point than most other serum proteins, ion exchange chromatography can be used for their purification. Practically, the matrix should be extensively washed with 0.5 mol L^{-1} HCl or 0.5 mol L^{-1} NaOH before use, and then equilibrated with the binding buffer. In addition, the sample must be dialysed against the binding buffer before being loaded on the resin.

At pH 6.5 (5 mmol L^{-1} phosphate), Igs will not bear negative charges, and therefore will not bind to a positively charged matrix such as diethylaminoethyl (DEAE) matrix, which is not the case for other serum proteins. A bulk Ig fraction can therefore be recovered in the flow-through. In contrast, Igs will bear a negative net charge at pH 8.5 (10 mmol L^{-1} Tris), and thus will bind to a positively charged matrix (DEAE). Sequential elution of proteins bound to the matrix can be performed by increasing the concentration of NaCl from 0.05 to 1 mol L^{-1} . Igs are among the first serum proteins to be eluted, at salt concentrations usually below 0.5 mol L^{-1} . Ig isotypes can be

differentially purified using this method. Relatively pure IgG is usually recovered in the first eluted fraction; IgM, the last eluted Ig isotype, may also be recovered in quite a pure form, whereas IgD and IgA, with intermediate elution properties, are only poorly resolved with this method. Ion exchange chromatography can yield sufficiently pure antibodies if the starting material is a cell culture supernatant or an ascitic fluid, but it must be coupled to an additional purification step when samples such as serum are used. The method is also cheap and is convenient for large initial volumes.

Hydroxyapatite Chromatography

Immobilized hydroxyapatite (calcium phosphate hydroxide) is used for another kind of adsorption chromatography. At pH 6.8, Igs bind to the matrix, and are eluted when a linear gradient of phosphate buffer from 120 to 300 mmol L⁻¹ is applied. When highly purified Ig fractions are needed, this technique must be coupled to another one, again depending on the starting material.

Gel Filtration Chromatography

A gel filtration matrix consists of beads containing pores of various sizes. As the sample flows through the matrix, the largest molecules are excluded from the beads. They stay only in the mobile phase, and move fast. The smaller molecules, depending principally on their sizes but also on their shapes, diffuse more or less inside the pores, and move more slowly within the column. Thus, this system allows the separation of the proteins according to their sizes and shapes. Various matrices with particular structures, pore sizes and excluding limits (the M_r at which the proteins are no more able to enter into the beads) are available commercially. Gel filtration can be used within broad pH ranges, with or without detergents such as 1% sodium dodecyl sulfate (SDS), or dissociating agents such as urea or guanidine. Ig purification is usually performed without sophisticated conditions, and allows the separation of IgM molecules that are considerably larger than IgG as well as many other serum proteins. Using an exclusion limit of 300–500 kDa, and a column volume of at least 20 times larger than that of the starting solution, IgM is easily recovered in the excluded peak. Due to the time needed to allow a complete passage, the use of a fraction collector is highly recommended. Fractions corresponding to 1–3 initial volumes should be collected. Gel filtration must usually be coupled with other methods to yield sufficient Ig purity, and is mainly limited to the purification of IgM.

Precipitation of Immune Complexes

The Precipitin Reaction

When antigens are added in adequate proportions to a mixture of antibodies, specific Igs and antigens will form a lattice which is susceptible to precipitate (the precipitin reaction). This macromolecular complex can then be easily recovered by centrifugation. The required amount of antigens to be added must be determined by establishing a precipitation curve. This implies that one should also have a procedure allowing the precipitate to be quantified. The use of radiolabelled antigens is particularly suitable for this when restricted amounts of antigens are available. Complement activation, which occurs in normal fresh serum, is able to inhibit the precipitation strongly. Therefore, it is necessary to make either a pre-purification of the Igs or to inhibit the complement cascade by the addition of ethylenediaminetetraacetic acid before performing a precipitin reaction. The precipitated lattice is subsequently re-solubilized either by incubation with serum or with an excess of free antigen, or by digestion with papain, which generates Fc fragments.

Polyethylene Glycol Precipitation

Soluble (nonlattice) immune complexes, either present naturally, or generated by adding a corresponding antigen, precipitate from serum in the presence of 3–4% polyethylene glycol (PEG; M_r 6000) after 2–12 h incubation at 4°C. This method has been widely used to isolate circulating immune complexes in various pathological situations. Other high molecular weight proteins, as well as aggregated Igs, can also precipitate using above-mentioned conditions. Therefore, additional steps of purification, using protein G or A (see below), are generally warranted before sufficiently pure material can be used. Solubilization of most PEG-precipitated immune complexes can easily be performed using most buffers that do not contain PEG. In contrast, dissociation of immune complexes requires quite harsh conditions, that are frequently not compatible with techniques allowing the further purification of free Igs devoid of antigens. Immunoprecipitation of specific antibodies is therefore mainly limited to analytical purposes that do not need biological activity. Ig light and heavy chains from immune complexes are easily solubilized in buffers containing SDS, and can be analysed by SDS-PAGE or 2D-PAGE.

Affinity Chromatography

In affinity chromatography, samples containing Igs are incubated in the presence of a matrix consist-

ing of an Ig-binding molecule covalently coupled to a bead support. Unbound molecules are removed by washing, and specifically bound Igs are then eluted using an appropriate buffer. The method is highly specific and high Ig purity is usually reached in a single step. Ig-binding molecules belong to three major groups: (i) bacterial protein A or protein G; (ii) specific antigens; and (iii) monospecific antibodies directed to epitopes on Igs (such as goat anti-human Ig antibody). Various bead supports and coupling procedures have been studied. The use of commercially available activated beads has now allowed preparation of affinity media within most laboratories. In particular cyanogen bromide (CNBr)-activated Sepharose beads can easily be used for most applications and detailed instructions are furnished by the manufacturers. After coupling, the resin should be extensively washed to remove all uncoupled Ig-binding molecule, and equilibrated in binding buffer. The binding capacity of each resin should be determined experimentally before use. If sample binding is indifferently performed in a container (batch procedure) fixed on a rotating wheel or through a column, washing and elution are best performed through a column. The use of a peristaltic pump is highly recommended to ensure a fixed flow.

Washing and elution steps are best followed online with a UV detector set to monitor at 280 nm. Alternatively, fractions may be collected and tested individually using either UV absorption or more specific procedures. When necessary (see elution conditions below), the eluate has to be collected in a neutralizing solution, and the resin immediately re-equilibrated in the binding buffer. Unused resins should be stored at 4°C in the presence of a bacteriostatic agent, such as 0.02% sodium azide or 20% ethanol.

Affinity Chromatography using Immobilized Protein G and A

Protein A and protein G are present within the bacterial cell walls of *Staphylococcus aureus* and of group G streptococci, respectively. Both proteins have high affinity for the Fc region of IgG, but bind differentially IgG subclasses from various species. Whereas protein G bind all human and mouse IgG subclasses, protein A presents only low binding capacity for human IgG₃ and mouse IgG₁. Ready-to-use matrix-immobilized protein G or A is commercially available, and detailed information about the binding properties of these two proteins can be found in the literature or furnished by the manufacturers. Binding buffers usually contain 100 mmol L⁻¹ Tris or 10 mmol L⁻¹ phosphate with 0.15 mol L⁻¹ NaCl, at pH 8 for protein A and pH 7 for protein G. After Ig

Figure 1 (A) 2D pattern of IgG purified over protein G-Sepharose. Human serum was incubated with commercially available protein G-Sepharose (Pharmacia), and IgG eluted as indicated in the text. γ heavy chains migrate within pIs ranging from 6 to more than 10, with a size of about 50 kDa. Light chains display pIs ranging from 5 to 10 and size between 21 and 26 kDa. γ , IgG heavy chain; κ , λ , light chains. (B) 2D pattern of IgA affinity purified over a homemade anti- α chain-Sepharose resin. The affinity resin was prepared from commercially available CNBr-activated Sepharose (Pharmacia), according to the manufacturer's recommendations, and commercially available goat anti-human α chain antibodies. α chains migrate with a pI ranging from 4.9 to 6.1 and a size of about 58 kDa. α , IgA heavy chain; κ , λ , light chains.

binding to samples, the resin is washed with about 20 vol of the binding buffer until online UV absorption of the flow-through medium gives an optical density back to zero. Elution of IgG is best performed by addition of 100 mmol L⁻¹ glycine pH 2–3 in tubes containing a suitable amount of a neutralizing buffer such as 1 mol L⁻¹ Tris, pH 8 or 1 mol L⁻¹ phosphate, pH 7. As illustrated in **Figure 1**, IgG is highly purified after a single-step procedure over protein G column, with no other heavy chain class detectable. The strength of the protein A(G)–Ig interaction, which is mainly based on hydrophobic

interactions, can be increased by raising salt concentrations of the binding and washing buffers to 3.3 and 3 mol L⁻¹, respectively. This high salt concentration method was initially described for the purification of mouse IgG₁ on protein A, but is now obsolete, due to the availability of protein G. The use of an excess of protein A allows IgG₁, IgG₂ and IgG₄ to be depleted from samples and IgG₃ to be purified using protein G in a second step. A sequential elution of all four IgG subclasses from protein A using a pH gradient has been described, but the resolution is quite low and subclass-specific purification of IgG₁₋₄ is now best performed using immobilized monospecific anti-Ig raised against either γ_1 , γ_2 , γ_3 or γ_4 heavy chains of the IgG molecule.

The elution yield from protein G or A using standard procedures is never 100% (see below) and residual IgG can be eluted during a second run procedure and may contaminate the new IgG being purified with IgG from the previous run. In order to avoid any Ig contamination from a previous experiment, it is therefore highly advisable to use either the same batch of protein G or A for the same initial IgG preparation or to use a new batch of resin for each procedure.

Affinity Chromatography using Immobilized anti-Igs

In this method, the immobilized binding molecules are Igs (mouse, rabbit, goat, sheep) directed against Ig heavy and/or light chains. Using antibodies of various specificities, it is possible to isolate either total Igs (using anti- κ and - λ chains), particular Ig isotopes (using anti- μ , - γ , - δ , - α or - ϵ chain) or IgG subclasses (using anti- γ_1 , - γ_2 , - γ_3 or - γ_4 chains). The interaction between immobilized and targeted immunoglobulins is just a particular type of antibody-antigen interaction. Binding and elution are therefore basically performed using the same conditions as those used for immobilized antigen supports (see below). Figure 1B shows that IgA purified from a human serum sample over an anti- α chain resin does not display any other heavy but α chain isotope. The resolution obtained by 2D-PAGE in separating various Ig heavy chains is illustrated in Figure 2.

IgG subclasses can be purified using two different procedures named positive and negative isolations. In positive isolation, the desired subclass is immobilized on a resin, washed and recovered by elution, whereas in the negative isolation, all unwanted subclasses are bound on resin and the desired subclass is recovered in the flow-through. The advantage of this latter approach is that the final preparation is not exposed to strong nonphysiological conditions which may denature the purified IgG sub-

Figure 2 (A) 2D pattern of a mixture of affinity purified IgM and IgA; (B) 2D pattern of a mixture of affinity purified IgM and IgG. Immunoglobulins were purified over homemade anti- μ chain-Sepharose resin, anti- α -chain-Sepharose resin and anti- γ -chain-Sepharose resin and mixed as indicated before electrophoresis. Resins were prepared according to the manufacturer's instructions, from CNBr-activated Sepharose and commercially available goat anti-human μ , α and γ chains. Immunoglobulins were prepared from serum as indicated in the text. μ chains migrate with pIs between 5.6 and 6.4, and size of 72 kDa. μ , IgM heavy chain; α , IgA heavy chain; γ , IgG heavy chain; κ , λ , light chains.

class. Disadvantages are that the methodology requires larger amounts of resin and several immobilized antibodies and that, when biological fluids are processed, the final preparation still contains proteins other than IgG.

Affinity Chromatography using Immobilized Antigens

A commonly used method for purifying and recovering antigen-specific, and antigen-free, Igs from a polyclonal mixture of antibodies involves the use of matrix-bound antigens that bind specific, antibodies at physiological pH and salt concentration

Figure 3 2D patterns of affinity purified anti-tetanus toxoid antibodies. Immunoglobulins were purified from two severe combined immunodeficient (SCID) mice (A and B) previously injected with human lymphocytes and boosted with tetanus toxoid. Homemade tetanus toxoid-Sepharose resin was prepared according to manufacturer's recommendations, from commercially available (Pharmacia) CNBr-activated Sepharose and a home preparation of tetanus toxoid. Igs were SDS-eluted, as indicated in the text. γ , IgG heavy chain; μ , IgM heavy chain; κ , λ , light chains, a, albumin.

(10 mmol L⁻¹ Tris or phosphate buffer saline (PBS) 0.15 mol L⁻¹ NaCl, pH 7.5). The unbound material is washed away with about 20 resin-volumes of binding buffer. Elution of bound antibodies is commonly performed by successive washes with 100 mmol L⁻¹ glycine, pH 2–3 and 100 mmol L⁻¹ triethylamine, pH 11–12. The eluted fractions are subsequently recovered into tubes containing neutralizing buffer. Elution solutions such as 5 mol L⁻¹ LiCl/PBS, 3.5 mol L⁻¹ MgCl₂/PBS, 1% SDS, 2–8 mol L⁻¹ urea, 3 mol L⁻¹ thiocyanate, 10% dioxane, or 50% ethylene glycol can also be used.

The purification of anti-tetanus toxoid Igs over a toxoid-coated resin is presented in Figure 3. Both 2D-PAGE light chain patterns shown depict a limited number of easily distinguishable spots, typical of oligoclonal Igs. These patterns are clearly different from that of total Igs (and purified total IgG, not shown) from the same serum, indicating that a subpopulation of Igs was purified. Whereas the anti-tetanus toxoid antibodies shown in Figure 3A

consist only of IgG, some IgM anti-tetanus toxoid antibodies were also present in the case shown in Figure 3B.

Affinity Chromatography Using Jacalin or Complement

Jacalin (a carbohydrate-binding molecule) allows the separation of both subclasses of pre-purified IgA (jacalin binds IgA₁ but not IgA₂). Complement C1q will bind antigen-complexed Igs. Anti-complement Igs will bind immune complexes bound to components of the complement system.

Recovery from Affinity Resins

As already mentioned, elution from protein G or A-Sepharose may be incomplete. In our hands, purification of 6–12 mg batches of IgG from various sources resulted in a recovery of about 50%, using acidic elution. Similar recovery yields have also been reported by others, using similar elution. Purification of anti-tetanus toxoid antibodies on tetanus toxoid-Sepharose resulted likewise in a 50% loss of antibody activity. We further investigated antibody recovery yield using affinity-purified radiolabelled antibodies. When purification was scaled down to 10 μ g Ig (an amount that allows enzyme-linked immunosorbent assay or electrophoresis techniques), recovery of bound material from protein G or tetanus toxoid-Sepharose was only about 10%. The percentage of lost Igs was roughly inversely proportional to the initial Ig amount. Some loss is acceptable when purifying large batches of monoclonal antibodies. On the other hand, when purifying antibodies for analytical purposes, one should keep in mind that antibody losses may skew the final results; the composition (isotype, subclass and diversity) of the eluted fraction may indeed no longer reflect the composition of Igs that were initially loaded on the resin. The problem of low recovery could be solved by heating Ig-loaded protein G- or tetanus toxoid-Sepharose in the presence of SDS and dithioerythritol; more than 97% of bound Igs could be recovered by this way. Of course, such treatment does limit further analysis to methods that do not require biological activity of Igs, such as electrophoresis, since Igs are denatured under such conditions.

Conclusion

Many different methods have been described over the years to purify Igs, and the most important have been briefly presented in this article. Of course, we have made a choice between the many methods available, and the list is not exhaustive. Numerous

Table 1 Summary of the major approaches for purifying immunoglobulins

Starting material	Methods	Purposes
Plasma, ascitis	Affinity chromatography on protein G or A	Isolation of pure IgG
Plasma, ascitis, pre-purified immunoglobulin fractions	Affinity chromatography on purified antigens	Purification of monospecific antibodies
Plasma, ascitis, pre-purified immunoglobulin fractions	Affinity chromatography using mono-specific antibodies (anti- α , - γ , - μ , - κ or - λ)	Isolation of immunoglobulins of a single isotype
Plasma, ascitis, pre-purified immunoglobulin fractions	(NH ₄) ₂ SO ₄ /DEAE Sepharose	Preparation of large amounts of relatively pure immunoglobulin fractions
Plasma, ascitis, pre-purified immunoglobulin fractions	(NH ₄) ₂ SO ₄ -Hydroxyapatite	Preparation of large amounts of relatively pure immunoglobulin fractions
Plasma, ascitis, pre-purified immunoglobulin fractions	Gel filtration/DEAE Sepharose	Preparation of relatively pure IgM fractions

variations and/or combinations of methods may be used to satisfy a particular need, depending on the starting material, as well as for the purpose of the purification. However, for most current applications, affinity purification procedures appear to be the most elegant and selective methods. The binding capacities of affinity resins are usually high (up to 20 mg of immunoglobulins per mL resin), and their reusability allows the purification of quite large amounts of pure immunoglobulins in relatively short times.

Table 1 summarizes the most efficient methods of purifying Igs.

Introduction

Isolation/purification of nucleic acids (NAs – dsDNA, ssDNA, tRNA, mRNA, etc.) is a common and crucial step in most molecular biology, biomolecule engineering, cancer research, recombinant DNA, forensic analysis, gene therapy, DNA vaccines and diagnostics (e.g. DNA chips) applications. Most often, NAs are isolated and purified merely as a way of obtaining quantitative and qualitative information about a certain sample (e.g. paternity testing, screening for viruses in clinical samples, etc.). Several purification methods have been developed by laboratories and companies involved in the above-mentioned areas. These protocols and processes are based on the same general principles, and follow three main stages: obtaining the NA source (cell growth, tissue isolation,

chemical or enzymatic reaction), primary isolation and purification. Different techniques exist that can be used alone or in combination within each step of the isolation/purification scheme (Figure 1).

When choosing an isolation/purification protocol or process, NA researchers and manufacturers should take into account several aspects. Especially important are the nature of the target NA, the final application, cost and availability of the technique (Table 1). The final application will determine which specifications (yield, purity, safety, efficacy, identity) the final NA preparation should follow.

Nucleic Acids

The success of NA purification relies on a minimal understanding of the molecular composition and structure of the target molecule. NAs are linear polymers of nucleotides (adenylate, guanylate, cytidylate and uridylate in RNA and deoxyadenylate, deoxyguanylate, deoxycytidylate and thymidylate in DNA) linked by phosphodiester bonds. The presence of negatively charged phosphate groups in the backbone of the molecule confers a polyanionic

nature to NAs. DNA molecules are often double-helix structures formed by two strands winding around each other and around a common axis. These structures are stabilized by hydrogen bonds and mainly by stacking forces. The helix axis can also be coiled, forming a higher order structure, named supercoiling. RNA can take on the same configurations as DNA, having secondary and tertiary structures; it can be single-stranded (more often) or double-stranded, linear (more often) or circular, and it can also form hybrid helices with DNA. Double-

stranded NAs melt to single strands fairly sharply as condition (temperature, OH⁻, denaturants like formaldehyde or formamide) becomes more denaturing. Renaturation is achieved when the reversible denaturation condition is removed. However, if the denaturation condition is quickly removed, the process is irreversible. The stability of double strands increases with the mole fraction of GC pairs and decreases as the pH is varied towards either side of neutrality. RNA is particularly sensitive to alkaline conditions.

Primary Isolation

Cell Disruption

Cells from the source organism are first recovered from the starting material, whether it is a cell culture, tissue or clinical sample, and resuspended in an appropriate buffer. The isolation of the target NA then starts with the disruption or lysis of the cells. There are several cell disruption methods that can be used alone or in combination (Table 2).

The choice of disruption method should consider factors such as the effect on the final NA, the cell type (animal or plant culture or tissues; fungi or Gram-negative or -positive bacteria spheres or filaments; viruses), the scale (laboratory- or industrial-scale), sample volume and number of samples, associated costs, duration and final application.

Usually, cell disruption is combined with a chemical or an enzymatic step for the inactivation of intracellular nucleases, which can degrade the target NA if a controlled method is not properly adopted. The physical and chemical conditions present during cell lysis are a key step in NA isolation. Temperature should be kept around 4°C to avoid nuclease activities that degrade the NAs. When an enzymatic step is included (performed at around 25–35°C), for instance by adding proteinase K or RNase to hydrolyse proteins or contaminating RNAs, caution should be taken with the presence of endogenous DNases that are active in the same temperature range.

The release of NAs during lysis significantly increases the viscosity of the solution, making mixing a difficult task. The lysates show non-Newtonian properties, exhibiting a rheological behaviour that makes flow and handling of the material very difficult. This issue is particularly troublesome on a large scale. The mixing at this stage should be very gentle to avoid shearing of the target NA. In certain proto-

cols and processes it is important to maintain the contaminating NAs with the highest molecular weight possible, in order to facilitate their removal in the subsequent steps. Glucose or sucrose is often included in the lysis buffer or after disruption, in order to protect NAs against shearing. Sensitivity to shear increases with molecular weight, and a single-stranded NA is more sensitive than a double-stranded one with the same length. Special care should thus be taken when handling (pipetting, pouring, mixing) NA solutions of high molecular weight.

The lysis buffer usually contains a chelating agent such as ethylenediaminetetraacetic acid (EDTA). The removal of divalent cations (mainly Ca²⁺ and Mg²⁺) from biological membranes and cell walls (when present) destabilizes their structure, facilitating lysis, and reduces the activity of endogenous Mg²⁺-dependent nucleases, preventing NA degradation. Protein-denaturing agents (e.g. detergents, phenol, guanidinium hydrochloride) are commonly added. The detergents denature proteins, including the ones associated with NAs, and solubilize lipids from membranes, facilitating cell disruption. Finally, the lysis buffer pH must be tightly controlled and local pH extremes avoided, since low pH values promote the hydrolysis of DNA, and alkaline pH favours the cleavage of RNA and the irreversible denaturation of chromosomal DNA. Moreover, very low pH values lead to depyrimidation and depurination.

RNA is notoriously susceptible to degradation and special care is required in its purification. The presence of endogenous and/or exogenous RNases is a major concern, since RNases can recover activity even after harsh denaturation treatments (e.g. boiling). High concentrations of strong chaotropic agents (e.g. guanidinium hydrochloride, guanidinium thiocyanate, caesium trifluoroacetate) is often used to inactivate RNases irreversibly and simultaneously promote the disruption of cellular membranes.

Table 2 Summary of cell disruption methods

<i>Physical</i>	<i>Chemical</i>	<i>Biological</i>
Pressure	Detergents	Enzymes
Ultrasound	SDS	RNase
Blades	Triton	Lysozyme
Grinding	Acid	Proteinase K
Freeze–thaw	Alkali	Viruses

	Chaotropic salts	
	Urea	
	Guanidinium hydrochloride	
	Guanidinium thiocyanate	
	Caesium trifluoroacetate	
	Thiol reduction	

Clarification of Lysates

After cell lysis and inactivation of endogenous nucleases, cellular debris, proteins and other precipitated molecules must be removed. This is usually achieved by means of centrifugation or filtration steps. During this operation, certain amounts of NAs can be lost in the liquid entrained in the solid phase. Extensive removal of water from the solid phase can be performed to increase the yield, but this operation usually also increases the amount of impurities. Minimum shear should be exerted in order to preserve the integrity of the target NA. The solution obtained after clarification is more or less rich in several impurities. Small molecules such as nucleotides, nucleosides,

amino acids, sugars and inorganic ions are easily removed, but DNA, RNA, polysaccharides and proteins are difficult to remove because these macromolecules have some common physical and chemical characteristics. The impurity profile and amount in a clarified lysate depend not only on the cell type, but also on factors such as phase growth and growth conditions (carbon and nitrogen sources, media richness, dissolved CO₂ and O₂, pH, etc), as well as on the method used for disruption (Table 2).

Purification

After the primary isolation steps, most impurities in solution are comprised of NAs from the source organism, denatured forms of the target NA, proteins and endotoxins (Gram-negative bacteria). The similarities between these molecules and their wide molecular weight range make purification difficult. Several methods are available to purify NAs, depending on the amount, yield and purity needed, and also on the availability of methods and associated costs.

Gradient Centrifugation

A classical method for separating DNA or RNA from each other, and from proteins and polysaccharides, uses equilibrium-density gradient (or isopycnic) centrifugation, which is based on differences in particle density. The density gradients can be self-forming or pre-formed continuous gradients, prepared with caesium salts (e.g. CsCl, Cs₂SO₄) or iodinated compounds (e.g. metrizoate, metrizamide, nycodenz). Equilibrium-density gradient centrifugation is one of the most efficient methods available for the purification of NAs. The major drawbacks are its dependence on high cost reagents and equipment (the ultracentrifuge) and the fact that it is a time-consuming operation (typically at least 48 h of centrifugation). When using this method, it should be kept in mind that centrifugal conditions may affect the native characteristics of the sample. For instance, the presence of endogenous and/or exogenous nucleases during a long-term process can lead to NA degradation. In addition, the chemical constituents of the solutions can affect the integrity of NAs. Physical degradation as a result of shear stress should be avoided, too.

The position of NAs in the gradient is usually located by measuring the absorbance at 260 nm. However, in a CsCl isopycnic separation, the DNA molecules band at approximately the same density. An alternative approach in this case is to band DNA in CsCl gradients in the presence of ethidium bromide or propidium iodide, which intercalate differentially between the bases of DNA, resulting in dif-

ferent molecule buoyant densities. This technique allows the separation of supercoiled plasmids, nicked or relaxed plasmid forms, genomic DNA, RNA and proteins.

Liquid-Liquid Extraction

Solvent extraction is often used to remove proteins and lipids from NAs. The pH values of the extractant organic phase and of the starting aqueous phase are very important because partition coefficients of NAs are pH-dependent. A classical system for solvent extraction uses a sequential extraction with phenol:chloroform (1:1). Although phenol is an efficient denaturant of proteins, it does not completely inactivate RNases, and it solubilizes RNA with long poly(A)⁺ tails. These problems can be partially overcome by introducing isoamyl alcohol in the phenol/chloroform mixture.

In spite of the efficiency of solvent extraction, residual contaminants still remain in solution. Furthermore, solvents like phenol and chloroform are extremely toxic for both the operator and the environment. Even small amounts in the final NA preparation are potentially toxic to live recipient cells and can interfere in downstream experiments. This makes solvent extraction an unacceptable method when preparing NA for therapeutic use.

Extraction of NAs has also been performed with aqueous two-phase systems. This technique relies on the fact that concentrated aqueous solutions of polysaccharides, such as dextran and polyethylene glycol (PEG), are immiscible. Many biological components (polymers, cells, cell organelles) including NAs show different solubility in the two phases formed, and will therefore separate by partitioning. By manipulating the system conditions (e.g. buffer, polymer and salt concentration) it may be possible to separate DNA from RNA, native from denatured DNA and single from double or triple strands. The technique, however, has not been studied in depth, and therefore is not commonly used.

Precipitation

Precipitation with ethanol or isopropanol is commonly used to concentrate NAs. Typically, 2 vol of ethanol or 0.7 (v/v) isopropanol is added to the NA solution. The process is more efficient if performed in the presence of moderate concentrations of monovalent cations and at low temperatures (below 4°C). The concentration and type of salt (cation: ammonium, lithium, sodium, potassium; anion: acetate, chloride) used in precipitation should be optimized for the target NA. The duration and speed of the centrifugation step used to recover the precipitate

material are also important, and should be adjusted according to the concentration of NA (longer and faster centrifugation for lower concentrations). If the amount of target NA is low, an inert carrier such as glycogen can be added to the mixture to increase precipitation efficiency. After draining liquid from the precipitated material, an appropriate buffer is added to redissolve the NAs.

Another method for precipitation of NA uses PEG/salt (NaCl, MgCl₂) systems. The method is based on the fact that the size of the DNA molecule precipitated by PEG is dependent on the concentration and molecular weight of PEG. It can thus be used either to fractionate DNA according to molecular mass, or simply to precipitate the total DNA content. The method is rapid and inexpensive but consistent yields are difficult to obtain.

The precipitation methodology, although generally used to concentrate NAs, is also effective as a purification step. Selective precipitation could be achieved, for instance, with high concentrations of different salts or changes in pH to precipitate proteins or nontarget DNA or RNA. For example, ammonium sulfate is often used to precipitate contaminating proteins. Lithium chloride precipitation has also been used in the preparation of large RNA. It takes advantage of the fact that small RNAs (tRNAs and 5S RNA) are soluble in solutions of high ionic strength, whereas large RNAs (rRNAs and mRNAs) are insoluble and precipitate out. After centrifugation, the high molecular weight RNA is redissolved in water or buffer.

Gel Electrophoresis

Gel electrophoresis on agarose or polyacrylamide gels is a powerful technique commonly used to separate, identify and purify NAs. Under the effect of an electrical field, NA molecules migrate through the gel matrix at a rate that is inversely proportional to their size. The resolving power of gel electrophoresis is extremely high, enabling the separation of molecules that differ in size by as little as 1 bp. The position of the individual molecules in the gel can be determined by staining with a fluorescent intercalating dye such as ethidium bromide. By using a number of techniques, such as electroelution or low-melting agarose gels, it is possible to recover DNA of high purity from the gels. However, the scale associated with electrophoresis is generally small.

Chromatography

Chromatography has been increasingly used to purify NAs. The technique is powerful, rapid and simple to perform, while avoiding the use of toxic compounds

common to competing technologies like ultracentrifugation and phenol/chloroform extraction.

Disposable column cartridges packed with particles of a stationary phase, and operating in the gravity flow format, often constitute an essential part of commercial isolation kits for lab-scale applications. In many cases, centrifugation is combined with disposable spin columns to enhance and speed the isolation. High-throughput and automated formats using these column cartridges are increasingly available that enable the processing of several samples at the same time, minimize hands-on preparation time, and reduce the risk of sample mix-ups. Purification using high pressure liquid chromatography (HPLC) has also been performed as a preparative step to isolate small quantities of NAs. In large scale applications, column chromatography is a central process step. For large scale applications, economic constraints demand regeneration and re-use of the expensive chromatographic media. Furthermore, if material is being produced for clinical use, validation of the cleaning is indispensable.

Different types of chromatography, such as gel filtration, ion exchange, hydrophobic interaction, reversed-phase, adsorption and affinity, have been used for the purification of NAs (Table 3).

Except in the case of gel filtration, the mode of operation of the chromatographic columns, whether small or large, is similar. Two possibilities exist:

1. Interaction of the target NA with the chromatographic support: column feed, binding of the target NA to the stationary phase, removal of impurities by washing and selective elution and, finally, elution of the target NA (Figure 2A).
2. No interaction of the target NA with the chromatographic support: column feed, collection of the target nucleic in the flow-through, binding of impurities to the stationary phase and, finally, column disposal or removal of the impurities by selective elution (Figure 2B).

A chromatographic column can also be used in conjunction with an enzyme process in order to improve the selectivity of the method. For instance, DNase (RNase) treatment of bound NAs will remove DNA (RNA), while leaving RNA (DNA) behind.

Purification by anion exchange takes advantage of the interaction between negatively charged phosphate groups in the DNA or RNA backbone and positively charged ligands on the surface of the particles that constitute the stationary phase. A salt gradient is usually used to displace the different NA species, which in principle should elute in order of increasing overall net charge, which in turn is a function of chain

Table 3 Purification of nucleic acids by chromatography

<i>Chromatography</i>	<i>Basis of separation</i>	<i>Examples and applications</i>
Anion exchange	Charge, charge density	Plasmid purification Plasmid copy number analysis Fractionation of restriction fragments
Hydrophobic interaction	Hydrophobic interaction	Separation of polymerase chain reaction products Separation of dsDNA from ssDNA and RNA Fractionation of supercoiled and relaxed plasmids
Reversed-phase	Hydrophobic interaction	Separation of dsDNA from ssDNA and RNA Separation of supercoiled and relaxed plasmid Purification of oligonucleotides (chemical synthesis)
Adsorption	Selective adsorption	Capture of nucleic acids by silica (glass powder, diatomaceous earth) Separation of dsDNA from ssDNA by hydroxyapatite Separation of RNA from DNA with boronic acids
Affinity	Structure recognition	Triple helix formation Hybridization of poly(A) ⁺ tails to oligo(dT) ligands Plasmid purification with acridine dye ligands
Gel filtration	Size, shape	Buffer exchange Salt and oligonucleotide removal Fractionation of supercoiled and relaxed plasmids Removal of endotoxins

length. When column cartridges are used, the salt gradient is always a step for convenience, while in process applications linear gradients can improve selectivity.

Anion exchange chromatography can also be used as a nonsize-based NA purification tool. In some cases, base sequence and composition affect the elution pattern of NAs in anion exchangers. The shape and size of the molecules may also play an important role. This is the case, for example, in the purification of plasmid variants. In some anion exchangers, the more compact supercoiled plasmid forms, which have a higher charge density, elute later than the open circular forms, which have a lower overall charge density.

Since many of the NAs being isolated are normally very large molecules, their binding to most of the existent anion exchangers is likely to occur only at the surface. This constitutes an important capacity limitation, especially in large scale applications. Different types of stationary phases have been used for anion exchange chromatography of NAs. Typical examples include weak ligands such as diethylaminoethyl and dimethylamino coupled to silica, polymeric or composite (inorganic + polymeric) matrices and strong ligands such as quaternary amines coupled to polymeric matrices.

Hydrophobic interaction chromatography has not been described for the purification of NAs, but recent results indicate that matrices derivatized with mildly hydrophobic residues are able to separate double-stranded DNA from RNA and single-stranded DNA under nondenaturing conditions.

In reversed-phase chromatography, NAs are also retained by the hydrophobic interaction of the bases with the chromatographic resin, but here, the density of ligands is much higher. Separation of single- and double-stranded DNA has been accomplished in C₁₈ columns and differentiation between DNA and RNA due to the effect of ribose and deoxyribose has also been reported. In reversed-phase chromatography, the binding is stronger than in hydrophobic interaction chromatography due to the higher ligand density. This requires elution to be carried out under more severe conditions, for instance, by using eluents with organic solvents, which can have a deleterious effect on the structure of the target molecule. For this reason, reversed-phase chromatography is more suited for the purification of smaller NAs that are less prone to denaturation. This is the case with synthetic oligonucleotides, used as primers or as blocking agents in antisense technologies, that are synthesized by solid-phase chemistry and purified by reversed-phase chromatography.

In adsorption chromatography, a stationary phase is used that selectively binds NAs in the presence of chaotropic salts, which remove water from hydrated molecules in solution, ensuring separation from complex biological mixtures. For instance, NAs adsorb to silica (glass) in the presence of sodium iodide or guanidinium hydrochloride, and to hydroxyapatite in the presence of urea. Polysaccharides and proteins do not adsorb and are removed by washing. Elution is performed using a low salt buffer. Hydroxyapatite further displays an ability to separate

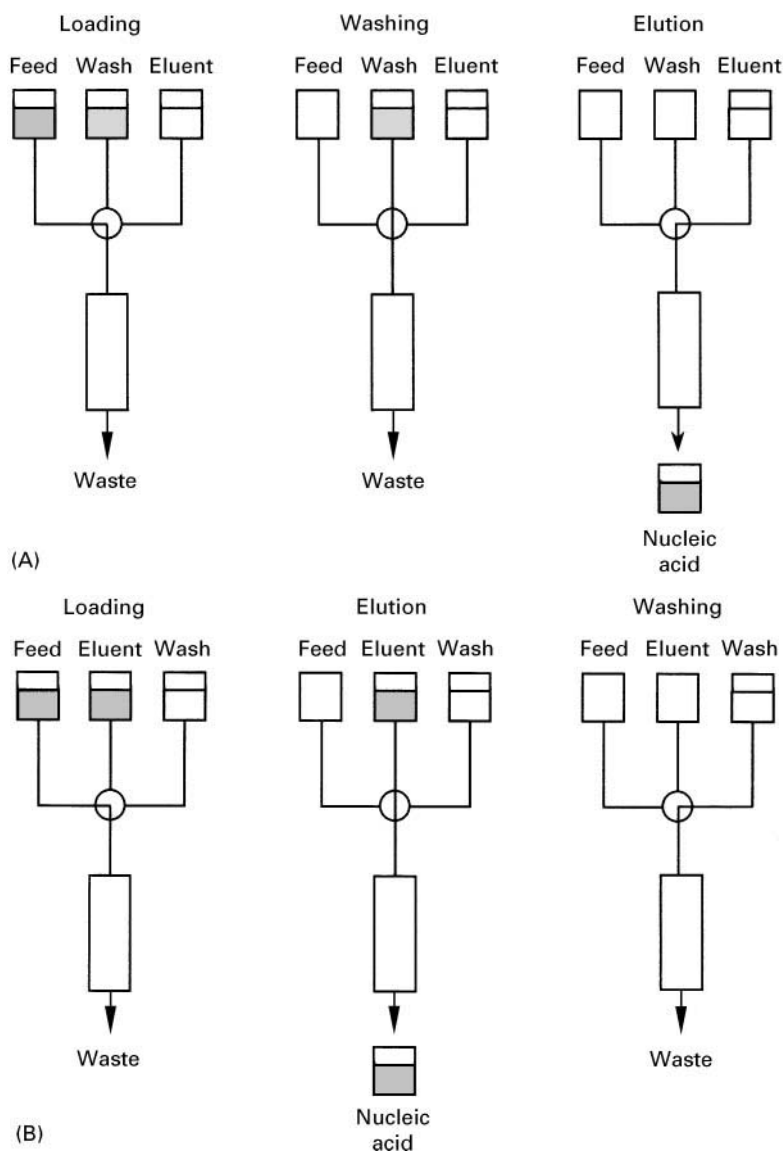

Figure 2 Mode of operation of chromatographic columns in nucleic acid purification: (A) interaction of the target nucleic acid with the chromatographic support; (B) no interaction of the target nucleic acid with the chromatographic support.

single-stranded NAs that bind less tightly from double-stranded NAs.

A method for the selective adsorption of RNA in the presence of DNA employs immobilized boronic acid derivatives which, above their pK_a values, form cyclic complexes with vicinal diols. Since the deoxyribose sugars lack the vicinal diol of ribose sugars in RNA, DNA is poorly adsorbed and can be washed away easily.

Affinity chromatography is based on the recognition of a particular structure in the target NA molecule by an immobilized ligand. In triple-helix affinity chromatography, the formation of triple helices between oligonucleotides linked to a chromatographic matrix and duplex sequences present on

dsDNA is explored. The affinity of poly(A)⁺ tails of mRNA to oligo(dT) probes has also been explored as a way of capturing and purifying mRNA. The combination of affinity ligands with magnetic particles is another recent development that avoids the use of packed columns. It allows the binding of the target molecule directly from solution, with the particle complex being recovered with a magnet. The high selectivity of affinity chromatography makes it a powerful tool for the one-step purification of NAs. However, since each ligand targets a specific base sequence, the versatility of the technique is low and the associated cost high.

Size exclusion or gel filtration chromatography has been used to fractionate NA molecules on the basis of

their relative size. By selecting a gel with an appropriate selectivity for the size range in question it is possible, for example, to isolate supercoiled plasmid DNA from microbial contaminants such as genomic DNA, RNA, proteins and endotoxins. Another feature of size exclusion chromatography, often explored when purifying NAs, is the possibility of exchanging buffers and removing salts, nucleotides, excess primers and other small molecules. This type of column is commercially available in the cartridge format for the clean-up of NA solutions.

Quality Control of Final Nucleic Acid

The final NA quality criteria will vary with the NA inherent complexity, its intended use and the method and complexity of manufacture. The researcher and/or producer will select several quality control tests that depend on their own application. NAs can be quantitatively and qualitatively analysed by a number of chemical, biochemical and physical assays. Some quality controls of NA preparations are summarized in Table 4.

A method used widely to estimate the amount of RNA or DNA is spectrophotometric analysis. The absorbance at 260 nm is relatively accurate (depending on base composition) and reproducible when applied to purified samples without significant amounts of contaminants (e.g. proteins, other NAs, phenol), and to moderately diluted or concentrated prepara-

tions. Spectrophotometric scans between 220 and 320 nm are also used to detect salt and organic contaminations. The purity of NAs based on the absorbance ratio 260 nm/280 nm is commonly used. A 260 nm/280 nm ratio between 1.8 and 2.0 is usually considered to be a good estimation of purity. This method was initially developed to quantify the contaminating NAs in protein preparations. For this reason, it often fails when used for NA purity assessment. Therefore, when a high level of purity is critical, care should be taken while using this method, and it should be complemented by other purity analysis. HPLC, capillary electrophoresis or methods using specific fluorescent dyes, quantitative DNA or RNA hybridization and quantitative polymerase chain reaction are preferable.

Conclusions

Isolation/purification of nucleic acids is becoming more and more important with the emergence of areas such as genomics, gene therapy and DNA vaccination and the growing importance of clinical diagnostics and forensics. The general strategies and technologies commonly used in the purification and isolation of NAs have been reviewed in this article. Critical issues and bottlenecks that still hamper the purification of nucleic acids have also been highlighted. Although the future will certainly bring more efficient isolation/purification methodologies, designed for high-throughput and automated preparation/analysis, the core technologies and strategies described here will most likely retain their importance.

Introduction

The isolation of polysaccharides from biological sources represents an important source of these valuable materials. Biomass such as cereal straws and grasses, are an enormous underutilized energy resource as raw materials in the production of paper, panel products, chemicals and other industrial products. On a dry-weight basis, the straws and grasses contain 65–85% of polysaccharides, with hemicelluloses ranked second to cellulose in abundance; however, it must be noted that the chemical content of the hemicellulose, with respect to saccharide ratios changes with plant growth and maturity (Table 1).

At the present time, there is widespread interest in the use of hemicelluloses, particularly arabinoxylan-rich hemicelluloses as precursors in food gums. More recently, water-soluble xylans from corn cobs have shown biological activity as immuno-modulating compounds. Other potential industrial applications of hemicelluloses are to be found in the fields of

adhesives, thickeners in foods, stabilizers, biodegradable film formers and emulsifiers. They can also be easily converted to primary chemicals such as xylose, xylitol, furfural, hydroxymethylfurfural and levulinic acid.

Hemicelluloses, however, are the most complex components in the cell wall of straws and grasses. They form hydrogen bonds with cellulose, covalent bonds (mainly α -benzyl ether linkages) with lignins and ester linkages with acetyl units and hydroxycinnamic acids. To investigate the potential utilizations of polysaccharides from straws and grasses, a thorough study of the isolation procedures is necessary. Details of the method are reviewed as follows.

Cell Wall Preparation

The straw or grass is cut into 1–2-cm lengths, air-dried, and ground to pass through a 0.5–0.8-mm screen. The ground sample is then further dried in a cabinet oven with air circulation at 50–60°C for 12–16 h. Dried material is dewaxed by refluxing with toluene–EtOH (2 : 1, v/v) or defatted with chloroform–methanol (2 : 1, v/v) for 6 h in a Soxhlet apparatus. The dewaxed sample is treated with α -amylase to degrade the starch or extracted with phenol–acetic

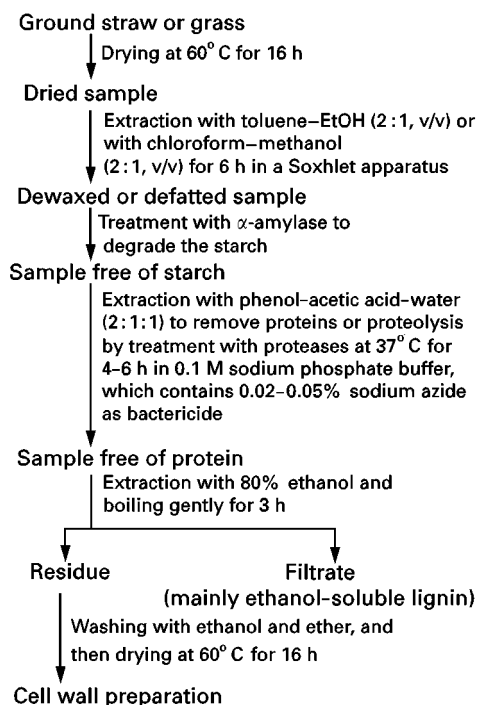

Figure 1 Scheme for procedures in cell wall preparation from straw or grass.

acid-water (2 : 1 : 1) to remove proteins. The proteins can also be extracted from the residue with sodium dodecyl sulfate solution containing 10 mM 1,4-dithiothreitol at room temperature for 3 h. To degrade the proteins, proteolysis is started by addition of proteases at 37°C for 4–6 h in 0.1 M sodium phosphate buffer, pH 7.5, containing 0.02–0.05% sodium azide as bactericide. The cell walls are recovered by filtration, extensively washed with water, and then treated with 80% ethanol to release the ethanol-water-soluble components. These consist mainly of free phenols and ethanol-soluble lignins together with small amounts of low-molecular-weight polysaccharides (~10% w/w of ethanol extract). After filtration, the cell wall preparations are dried by solvent exchange through ethanol and diethyl ether. Figure 1 summarizes the procedures for cell wall preparation.

Fractional Extraction of Cell Wall Polysaccharides

Water-Soluble Polysaccharides

The scheme for fractional extraction of cell wall polysaccharides is illustrated in Figure 2. The prepared cell walls are stirred with distilled water at 75–80°C for 2 h. The residue is filtered off on a nylon cloth, washed with ethanol and ether, and dried in an

oven at 60°C for 16 h. Water-soluble polysaccharides are isolated by precipitation of the concentrated supernatant with 4 volumes of 95% ethanol and recovered by centrifugation. The resultant solid is subsequently purified by extensive washing with 75% ethanol and then freeze-dried. As shown in Table 1, water-soluble polysaccharides obtained from various straws and grasses account for 3.7–6.8% of the dry matter and have much lower weight-average molecular weights ($\bar{M}_w = \sim 8000 \text{ g mol}^{-1}$) when compared to those of hemicellulosic fractions. Neutral sugar analysis shows that arabinose and galactose are the major sugar constituents, whereas xylose and glucose are present in only small amounts in this fraction. Detailed studies of water-soluble polysaccharides from rapeseed meal, sorghum stalk, and dehulled legume seeds and their hulls have been reported.

Pectic Polysaccharides

The pectic polysaccharides are restricted to the primary cell wall and middle lamella of higher plant tissues and growth zones. They are most abundant in soft tissues, such as rinds of citrus fruit (~30%), sugar beet pulp (~25%), and apple peels (~15%), but are present in only small proportions in woody

Figure 2 Scheme for fractional extraction of polysaccharides from straw or grass.

tissue such as straw and grass (0.5–1.5% dry matter). The term ‘pectins’ or ‘pectic substances’ is associated with acidic polysaccharides consisting of a backbone of mainly (1 → 4)- α -bound D-galacturonic acid residues interrupted by the insertion of α -linked L-rhamnose residues. Other constituent sugars such as L-arabinose, D-galactose, D-xylose, L-fucose, and traces of 2-O-methyl-D-xylose and 2-O-methyl-L-fucose are attached in the side chains. The pectins can be extracted with dilute acid, e.g. HCl solution at pH 1.5 or with chelating agents such as 0.2% aqueous ammonium oxalate, disodium ethylenediaminetetraacetic acid (EDTA), and sodium hexametaphosphate (SHP) solution at pH 3–4 for 4 h at 85°C. After extraction, the filtrates are adjusted to pH 4.0 with 1 M NaOH. The pectic polysaccharides are isolated by precipitation of the filtrates in 4 volumes of 95% ethanol and recovered by centrifugation. Crude pectins are extensively washed with 70% acidified ethanol and fractionated by ion exchange chromatography on a column (550 mm × 15 mm) of DEAE Sepharose Fast Flow (Pharmacia, Sweden), initially equilibrated in 0.005 M NaAc–buffer pH 5.0 or on a QAE Sephadex A-25 column (80 × 1.5 cm i.d.; Pharmacia, Sweden) equilibrated with 10 mM imidazole-HCl buffer (pH 7.0). Other columns used to fractionate the pectic polysaccharides include a DEAE-Sepharose CL6B column (23 × 5 cm; Pharmacia, Sweden) equilibrated with 0.005 M sodium succinate buffer at pH 4.8, and a DEAE-Sephadex A-50 column (20 × 2 cm; Pharmacia, Sweden) previously equilibrated with 10 mM potassium phosphate buffer (pH 6.0). The neutral and acidic pectic polymers are hydrolysed with 2 M trifluoroacetic acid at 120°C for 2 h in sealed ampoules or with pectinase. In comparison, treatment by pectinase has a significant effect on the hydrolysis of the pectic polymers, while the reverse trend is observed during the treatment of the neutral pectic polysaccharides by acid hydrolysis, since galacturonic acid residues in polysaccharides are known to be resistant to acid hydrolysis. For example, endo-1,4- α -polygalacturonase, pectin and pectate lyases can substantially cleave the α -(1 → 4)-GalpA glycosidic bonds between contiguous galacturonic residues. Previous studies have shown that extraction of the cell wall preparation of sugar beet pulp with water followed by treatment with HCl at pH 1.5, 0.2% ammonium oxalate, 0.2% EDTA, and 0.2% SHP at pH 3.3 for 4 h at 85°C yielded 32.1%, 26.1%, 29.3%, and 30.0% (percent dry cell wall preparation) of pectic polysaccharides, respectively. An optimum extraction procedure was found to be treatment with dilute HCl at pH 1.5 for 4 h at 85°C, in which the pectin contained 84.6% anhydrogalacturonic acid

and only 2.7% ash. Xylose-rich pectic polysaccharides (1.1% of dry matter) can be obtained from wheat straw by extraction with dilute HCl at pH 1.6 for 4 h at 85°C, which contain 44.8% galacturonic acid (released by pectolyase), and 28.4% neutral sugars (released by acid hydrolysis).

Hemicelluloses

The cell wall components that are readily hydrolysed by hot dilute mineral acids, or dissolved by hot dilute alkalis or cold 5% sodium hydroxide solutions have been termed ‘hemicelluloses’. Hemicelluloses belong to a group of heterogeneous polysaccharides which are formed through biosynthetic routes different to the glucose-UDP route of cellulose (a homopolysaccharide). Hemicelluloses of Gramineae such as cereal straws have a backbone of (1 → 4)-linked β -D-xylopyranosyl units. The chain may be linear, but is often branched and usually has other glycosidically bound sugar units. Some xylan chains have D-glucopyranosyluronic acid units attached, but the most important acidic hemicelluloses are O-acetyl-4-O-methyl-D-glucuronoxylans and L-arabino(4-O-methyl-D-glucurono)xylans. In dicots, where the hemicelluloses are mostly xyloglucan, hydroxyproline-rich glycoproteins also comprise a substantial amount of the cell wall and cross-link the carbohydrate polymers to form a rigid matrix. In cereal straws of grasses, these proteins have been replaced by esterified and etherified phenolic compounds. The xylans present in the hemicellulosic backbone can be substituted by arabinose, galactose, glucuronic acid, and methyl glucuronic acid. The arabinoxylan can be isolated directly from fully lignified straws or grasses by extraction with aqueous potassium hydroxide or sodium hydroxide. Usually 80–95% of the total xylan present in straw and grass contains a relatively high percentage of associated lignin (5–10%). This high lignin percentage considerably darkens the polysaccharide limiting their industrial application.

Xylans undergo only partial hydrolysis in alkaline solution at room temperature under an atmosphere of nitrogen. The product obtained – except for the fact that acetyl-, feruloyl-, and *p*-coumaroyl appendices have been partially or completely saponified – is quite similar to the native polysaccharide. The hemicelluloses which have a light brown colour contain a relatively small amount of bound lignin (1–2%), and can be quantitatively isolated from the holocellulose by extraction with aqueous alkali. Delignification of the depectinated cell wall preparations obtained from straws or grasses has been performed with sodium chlorite at 75°C for 2 h in acidic solution

(pH 4.2–4.7) adjusted by 10% acetic acid. The acetylated xylans are soluble in water and in solvents such as dimethylsulfoxide (DMSO), formamide, and *N,N*-dimethylformamide. Although only a part of the xylan can be extracted, the advantage is that no chemical changes take place. Aqueous solutions of potassium and sodium hydroxide are mostly used as the alkaline solvent of choice for the extraction of hemicelluloses. The preferred hydroxide is potassium, mainly because the subsequent potassium acetate formed during the neutralization is more soluble in the alcohol used for precipitation than is sodium acetate. Comparison of the extraction ability of 1 M solutions of potassium, sodium, and lithium hydroxide on wheat straw, shows an approximately equal effect in the rate and yield of solubilization of hemicellulose. However, it has been found that sodium hydroxide and lithium hydroxide are more powerful than potassium hydroxide in removing hemicelluloses, especially mannans from wood samples. The yield of hemicelluloses obtained using calcium hydroxide and liquid ammonia was markedly lower than for the respective alkali metal hydroxide solutions. Liquid ammonia, in general, can be used for pre-swelling prior to an alkaline extraction. Moreover, the yield of hemicelluloses strongly depends on a number of important factors, e.g. type of alkali, concentration, temperature and time of extraction. Addition of sodium borate to the alkali facilitates the dissolution of galactoglucomannans and glucomannans. However, any ester groups present are simultaneously saponified during the alkali extractions.

Hemicelluloses obtained by alkali can be subfractionated into hemicellulose A, B, and C. Hemicellulose A, the more linear and less acidic fraction, is isolated from the supernatant by acidifying to pH 5.0 with acetic acid followed by centrifugation. Hemicellulose B, the more acidic or branched fraction, is obtained from the mother liquor by precipitation with 4 volumes of 95% ethanol, then filtered and

washed with 70% ethanol. The resultant solid is redissolved in water (after the residual salts were dialysed against water until free from salts), and the hemicellulose B recovered by evaporation under reduced pressure at 45°C or by lyophilization. The fraction that remains soluble in aqueous ethanol is named 'hemicellulosic fraction C' and is isolated by dialysis with water and ethanol until free from salts (Figure 2). The yield and neutral sugar composition as well as content of uronic acids of hemicellulosic subfractions of DMSO-solubles, A, B, and C extracted sequentially by DMSO at 80°C for 2 h and 10% KOH–2% H₃BO₃ at 25°C for 16 h from wheat straw holocellulose, are given in Table 2.

Precipitation of the polysaccharide fractions by addition of miscible organic solvents to aqueous solutions is one of the main methods of recovery and purification. Ethanol is the solvent most commonly used, but methanol, acetone, and other organic solvents have also been applied for fractionation of hemicelluloses. In ethanol–water (80:20, v/v) the major portion of the polysaccharides are precipitated and only a small amount of short-chain material is left in solution. In addition to the neutral organic solvents, some more specific precipitation agents are also known, e.g. barium hydroxide for glucomannans and cetyltrimethylammonium bromide or hydroxide for glucuronoxylans. Fehling's solution or other copper salts can be used for precipitation of both glucomannans and glucuronoxylans. Hemicellulosic complexes precipitated by iodine in calcium chloride appear to be relatively unsubstituted by non-xylose residues, whereas the material remaining in solution is more highly substituted by such residues. The methods used to fractionate the hemicelluloses of straws and grasses are similar to those used to fractionate hemicelluloses from woods. The hemicelluloses may be fractionated as their acetates by precipitation from solution by ammonium sulfate, or by chromatography on DEAE-cellulose. The

precipitated hemicellulose preparations can if desired be further purified by column chromatography.

Gel permeation chromatography is one of the most useful tools for determining the average molecular weights of the isolated hemicellulosic fractions. Ion exchangers based on cellulose, dextran or agarose such as diethylaminoethyl cellulose in different ionic forms can also be used to separate hemicelluloses from each other. Chromatography (in its various forms) is routinely used for the characterization of the acidic hydrolysis products of isolated hemicelluloses. Dialysis of aqueous solutions often removes inorganic salts and other low-molecular-weight impurities prior to chromatography. Alternatively, salt may be removed by electrodialysis, by treatment of solutions with ion-exchange resins, or by gel filtration, using Sephadex, a cross-linked dextran column.

More recently, it has been reported that alkaline peroxide is an effective agent for both delignification and solubilization of hemicelluloses from straws and grasses. This was first proposed in 1984 in studies on the alkaline peroxide delignification of agricultural residues to enhance enzymatic saccharification. Hydrogen peroxide is widely used in the pulp and paper industry to bleach lignin-rich pulps. It has been generally accepted that the bleaching action of hydrogen peroxide is attributable to the hydroperoxide ion (HOO^-), formed in alkaline media, which is the principal active species in hydrogen peroxide bleaching systems. This anion is a strong nucleophile that preferentially attacks ethylenic and carbonyl groups present in lignin. On the other hand, hydrogen peroxide is unstable in alkaline conditions and readily decomposes, particularly in the presence of certain transition metals such as manganese, iron, and copper. This metal-catalysed decomposition of hydrogen peroxide is undesirable in the bleaching operation. However, this decomposition generates more active radicals, such as hydroxyl radicals (HO^\bullet) and

superoxide anion radicals ($\text{O}_2^{\bullet-}$), participating in degradation reaction of lignin and solubilization of hemicelluloses, which therefore, results in significant solubility of the lignin and hemicelluloses. The advantages of hemicellulose extraction with alkaline peroxides are low investment cost, accompanying strong bleaching effect, lower biological and chemical oxygen demand (BOD and COD) effluents as well as the recovery of the solubilized macromolecular hemicelluloses with a minimal degradation. Results show that more than 80% of the original hemicelluloses and over 90% of the original lignin is solubilized during the treatment of cereal straws such as wheat, barley, rice, oat, and rye straw, and maize stems with 2% H_2O_2 at 48°C for 16 h at pH 12.0–12.5 (Table 3). These hemicellulose preparations are white in colour and contain very small amounts of associated lignin (3–5%).

To gain maximum dissolution of the hemicelluloses, it is not necessary to continuously regulate the reaction pH, even though over the course of the treatment (48°C, 16 h) the reaction pH rises from 12.0 to 12.5 and from 12.9 to 13.1, respectively. As the reaction pH becomes more alkaline, increasing amounts of hemicelluloses are solubilized, and the yield of the residue decreases. Incremental increase of the initial reaction pH from 11.5 to 12.5 results in an increase of hemicellulose dissolution of about 20%. During the initial stages of stirring, oxygen evolution is active, and substantial frothing occurs, requiring extractions to be conducted in vessels with volumes two to three times those of the extraction mixtures. After treatment, the cellulose-rich insoluble residue is collected by filtration, washed with distilled water until the pH of the filtrate is neutral, and then dried at 60°C. The supernatant fluid is adjusted to pH 5.5 with 10% HCl and then concentrated. The solubilized hemicelluloses are precipitated by pouring the concentrated supernatant into 4 volumes of

that the alkaline peroxide treatments under the conditions given do not affect the overall structure of the macromolecular hemicelluloses. This effective and convenient method of alkaline peroxide treatment may be used for most isolation of hemicelluloses from straws and grasses.

Steam treatment enables the lignocellulosic materials present in straws and grasses to be separated into hemicelluloses, lignin, and cellulose in reasonable yields and purity. Steam-explosion treatments or other steam treatments have the advantage of using a widely-available solvent without significant cost or environmental impact. It is generally agreed that the steaming process is basically an acid-catalysed autohydrolysis due to the small amounts of acetic acid liberated early in the process through cleavage of the hemicellulosic acetyl groups. A portion of the starting material, mainly hemicellulose, is converted into water-soluble products through this acid-catalysed hydrolysis process. The cellulose is not significantly solubilized but undergoes a change in its crystallinity or is partially depolymerized. During this process, the lignocellulosic substrate is steam treated at temperatures ranging from 140 to 240°C for 1–10 min followed by a rapid pressure release (i.e. explosion) through a discharge valve. The hemicelluloses solubilized during the steam or steam-explosion process, are isolated after extraction in water. They comprise mainly acetyl- and 4-O-methylglucuronosyl-substituted xylans, and contain 15–25% and 5–10% bound lignin, respectively. The associated lignins can be removed by treatment of the crude hemicelluloses with 1 M NaOH at 20°C for 2–4 h. All the hemicellulosic preparations have a lower degree of polymerization (40–65), with \bar{M}_w ranging between 5000 and 10 000 g mol^{-1} .

Cellulose

Cellulose is the main constituent of agricultural residues. Approximately 35–45% of the dry substance in most straw and grass species is cellulose, located predominantly in the secondary cell wall. The term ‘ α -cellulose’ is given to the residue remaining after delignification by sodium chlorite in acidic solution and separation of hemicelluloses by extraction of the holocellulose with 24% KOH (or 17.5% NaOH) at 25°C for 2 h or 10% KOH (or 7.5% NaOH) at 25°C for 16 h. This term was originally coined for wood cellulose which is insoluble in strong sodium hydroxide solution. The portion which is soluble in the alkaline medium but precipitated from the neutralized solution was called ‘ β -cellulose’. ‘ γ -Cellulose’ is the name for the portion which remains soluble even in the neutralized solution. This method was

modified in various ways and is now established as the standard method for the determination of α -, β -, and γ -cellulose from straws and grasses. The cellulose-rich residues remaining after alkaline peroxide treatment under the conditions given earlier contain 80–90% cellulose and 10–20% hemicelluloses as well as approximately 5% bound lignin. During steam treatment, cellulose undergoes a change in its crystallinity and can also partially depolymerize, depending on the treatment conditions. The cellulose-rich fibres generated by the steam treatment/explosion process are generally more accessible to chemicals and enzymes under derivatization conditions.

Further Developments

The current views on the fractional isolation of polysaccharides from cereal straws and grasses are based on the culmination of information gained over the past thirty years. In spite of the many studies on the polysaccharides of straws and grasses, little is known about (a) isolation of pectic polysaccharides, (b) isolation of the polysaccharide fraction present in delignification liquors, and (c) isolation of non-glucosyl residues and residual lignins in α -cellulose. Procedures designed to extract pectic substances may extract material that might otherwise be described as partly hemicellulosic, and the converse may also happen. Many procedures used in the isolation of polysaccharides from straws and grasses would lead to the loss of any such polysaccharides present. During delignification of wheat straw with sodium chlorite in acidified solution, 1.2–2.4% of the total hemicelluloses passes into solution. It is also more difficult to isolate pure cellulose without degradation since the hemicelluloses and lignin are strongly associated with cellulose; many of the solubilized hemicelluloses are irreversibly absorbed on the cellulose. In addition, drying straw and grasses in an oven at 60°C may cause autohydrolysis or other changes in polysaccharide morphology. Furthermore, the various procedures used prior to the exhaustive extraction of hemicelluloses may affect quantitative or structural conclusions about the hemicelluloses as they

occur in nature. It is also of interest to note that the hemicellulosic materials extracted by alkali are, only in part, precipitated in ethanol after neutralization of the extract. Under these conditions, a small part of the hemicellulosic materials remains in solution, and is commonly not recovered. All of these points require further investigation to obtain a more reliable standard method for fractional isolation of polysaccharides from cereal straws and grasses.

Introduction

Highly selective affinity-based separations have evolved considerably over the past two decades to improve characteristics related to target specificity, dynamic adsorptive capacity and chemical robustness of the affinity matrix. These separation matrices are used as screening devices for molecular interactions as well as for the purification of complex mixtures at the analytical, preparative and large scale. Affinity adsorptive phases can be synthesized by the attachment of structures called ligands to immiscible polymeric fluids, solvated gels and porous solids. Ligands are selected for their affinity to a soluble or colloidal target species. Advances in technology have been associated with the synthetic and biosynthetic design of affinity ligands and matrices. These advances have been made through a better understanding of phenomena associated with the transport of the target species to the ligand and the nature of molecular interactions between target and ligand. Specialized processing equipment for large and small scale applications has also improved affinity separations.

Matrix Materials and Processing Geometries

Separations achieved by the selective capture of a target from a fluid phase by an affinity ligand confined to an adsorptive phase are most often done in aqueous systems. Therefore, the adsorptive phase for a hydrophilic target species is often a hydrophilic material. More hydrophobic targets require matrices which offer a more hydrophobic environment. In some cases, the adsorptive phase can be a separate fluid phase or soluble component having affinity ligands which will capture and concentrate the target species from complex aqueous mixtures.

Mattiasson demonstrated that heterobifunctional ligands could be used for selective isolation of proteins by affinity precipitation. Heterobifunctional ligands can bind the target and are also covalently coupled to a polymer which can be used to induce precipitation of a target/ligand complex. Alternatively,

multiple but identical binding sites can be occupied on the target by homobifunctional ligands. This results in a cross-linked network between targets which can be precipitated. Polymers used for affinity precipitation applications include chitosan, alginate, polyethyleneimine, and Eudragit S-100 (a copolymer of methyl methacrylate and methacrylic acid). By manipulating such parameters as the pH or temperature, the polymer/ligand/target complex can be reversibly rendered soluble and insoluble. Lactate dehydrogenase and alcohol dehydrogenase have been precipitated using Cibracron Blue 3GA coupled with EudragitTM S-100.

A significant advance in the field of bioseparations is the coupling of affinity ligands to aqueous two-phase systems of water-soluble polymers. Affinity partitioning is the selective extraction of target proteins from crude mixtures using affinity ligands immobilized on to either of two incompatible, water-soluble polymer phases. Mattiasson used triazine dyes coupled to immiscible polymer fluids to purify proteins by affinity partitioning. Reactive triazine dyes have been widely exploited using this separation technique. In comparison to classical chromatographic systems, affinity equilibrium is attained more rapidly in aqueous two-phase partitioning. In addition, high affinity binding capacities and protein recoveries have been achieved. Alternatively to two-phase aqueous polymer partitioning, McCreath and Chase immobilized human immunoglobulin G on to perfluorocarbon emulsions for the selective adsorption of *Staphylococcus aureus* cells containing membrane-bound protein A. These liquid emulsion droplets were comprised of a perfluorocarbon oil cross-linked with poly(vinyl alcohol).

Most of the applications for affinity-based separations are developed for chromatographic processing of aqueous systems. Thus, the ligand is immobilized on a porous bed of solids packed in a column through which liquid can be pumped. Most of the matrices are made of hydrogels composed of cellulose, agarose and dextran. A chief advantage of hydrogel matrices is the combination of an easily derivatized, hydrophilic environment that provides molecular accessibility that can be extended to 10⁶ Da. Other semi-synthetic and synthetic polymeric matrices, such as copolymers of vinyl dimethyl azlactone and methylene-bis-acrylamide, can also provide similar

intraparticle transport features. Coleman immobilized protein A at high density on to azlactone-functionalized polymeric matrices. These affinity matrices demonstrated high throughput capacity combined with low operating pressures. As an alternative to the use of pellicular matrices or matrices comprised of reduced bead particle diameter, Rodriguez and Liapis described the mechanism of perfusion chromatography in which intraparticle mass transfer resistance is reduced by increasing the particle permeability. Velander optimized the molecular accessibility and mechanical stability of uncross-linked cellulose adsorbents by using large diameter beads (>0.3 mm) which operate at low pressures even at high flow rates. These hydrogel matrices had a solids content of only 3% or less and were shown to provide fast intraparticle transport, apparently through a mixed mode of both diffusion and convection. Larsson demonstrated the use of superporous agarose matrices. The agarose beads contained a typical internal porous network in addition to larger pores. These larger pores constituted a significant portion of the bead, up to one-third to one-tenth of the bead particle diameter. Mass transfer characteristics were improved since the larger pores allowed a considerable fraction of the bulk chromatographic flow to penetrate and flow through the individual bead particles. Affinity matrices were prepared using these superporous agarose beads containing immobilized NAD^+ analogue for the isolation of bovine lactate dehydrogenase and protein A for the isolation of rabbit immunoglobulin G. These affinity matrices operated under much higher processing flow rates compared to conventional homogeneous bead columns. The protein A and NAD^+ analogue matrices had processing throughputs five and three times higher, respectively, in comparison to processing throughputs demonstrated by conventional affinity matrices. Thus, a significant improvement to affinity technology is the design of matrices having greater intraparticle accessibility and transport of the target species.

Advances in transport phenomena needed for target contacting with the affinity adsorbent have resulted in matrix designs having large or small particulate as well as membrane geometries. Smaller particles, having mean diameters of about 0.1 mm or less, yield a greater surface area to volume for improved target mixture contacting, but higher drops when operated in a packed bed mode. Thus, specialized affinity separations using high pressure liquid chromatography have been developed for small and large scale. However, these media require pre-clarification of the feed stream before chromatographic processing to prevent column fouling. Alternatively, small diameter particles having a higher density than water can be

fluidized to achieve both filtration and affinity adsorption in a single step using expanded bed chromatography. Expanded bed adsorption chromatography has been developed to provide single stage operation for the isolation of target proteins from crude mixtures such as milk, hybridoma cell culture fluid and fermentation broth. For example, humanized IgG4 antibody was isolated from myeloma cell culture fluid by expanded bed adsorption using recombinant protein A immobilized on to Pharmacia StreamlineTM media.

Planar membranes are often used for affinity separations in analytical assays but some cross-flow, stacked sheet geometries have been developed for large scale applications. Affinity membranes for large scale work can also be cast in tubular hollow fibres. One example of planar membranes was made of a gel formed from two dispersed liquid phases. The chief advantages of affinity membrane systems are the low pressure operation and fast intraparticle transport due to the short diffusion distances in thin membranes. Thus, the kinetics of ligand/target interactions can become rate limiting to affinity separations using thin membranes. Etzel showed that limitations in membrane performance can arise due to variations in porosity and thickness which can result in diffuse breakthrough loading profiles. The stacking of planar membranes can sharpen affinity breakthrough profiles at higher loading flow rates.

Affinity Ligand Selection and Design

Affinity ligands have evolved from antibodies, enzymatic substrates, co-factors, nucleic acids, coenzymes, hormones, immunoglobulin, lectins, effectors and inhibitors to a great diversity of small, low molecular weight peptides, polypeptides and other organic structures. These newer classes of ligands can be made using biosynthetic and wholly synthetic methods. Common to all selection strategies is the need to begin with a diversity of structures from which to discover candidate affinity ligands. The chance discovery of a ligand with desirable properties has been enhanced through the use of phage display and synthetic combinatorial libraries which contain many orders of randomized structural permutations. The structural permutations within a library rely on the polymeric assembly of bi- or multifunctional monomeric molecules into compounds which are typically greater than 10^3 Da in molecular mass. In the case of biosynthetic libraries, the assembled structures are necessarily polypeptides and the subunits are amino acids. In the case of wholly synthetic structures, a variety of bi- and multifunctional organic

subunits that provide high selectivity and yield reactions have been sequentially assembled using soluble or solid-phase linked chemistries. For example, various perturbations of bifunctional molecules having reactive oxazoline chemistry have been used to create assembled combinatorial chemical libraries having 10^3 or more structures. In addition, some wholly synthetic libraries have used amino acids and novel branched chain peptide linkages as core structural platforms.

In 1985, Smith demonstrated the use of phage technology to display candidate polypeptide ligands from a bacterial virus particle which also contains the DNA encoding the polypeptide sequence. The polypeptide is displayed from the virus particle surface in a manner that also enables affinity interactions with a targeted species. Thus, candidate ligands can be screened by the specific adsorption of phage to target species which have been immobilized either to a microtitre assay plate or to a chromatographic matrix. Nonspecifically adsorbed material is then washed away and the specifically adsorbed phage particles are eluted. The eluted phage particles are cultured using microbiological plate-streaking techniques. Candidate phages from the first affinity screening are passed through a second affinity screening and reculturing. Phages obtained from the two affinity and culture selection processes are subjected to DNA sequencing. The DNA sequence of the displayed polypeptide is readily determined because of specific endonuclease restriction sites engineered into the phage genome. The polypeptide ligand DNA sequence then is readily used to create ligands in mass quantity through recombinant fermentation technology. About 10^8 polypeptides can be created within a single phage display library where about 10^1 to 10^2 candidate ligands typically result after a sequence of two affinity and culture screenings. Thus, the chief advantage of the biosynthetic phage display libraries is the large number of library members and facile screening due to the coupled nature of the encoding DNA and displayed polypeptide ligand of the phage particle. The chief disadvantage is the inherent limitation to structures which are polypeptides. However, as a further improvement of phage library technology, Ladner demonstrated that the use of random permutations about a core polypeptide ligand sequence can greatly enhance the affinity of initial ligand candidates. The chemical robustness of polypeptides is typically limited to moderate pH and aqueous environments.

Examples of the use of phage-display libraries in the development of affinity ligands are found throughout the recent literature. Ladner generated a series of libraries comprised of variants of the first

Kunitz domain of human lipoprotein-associated coagulation inhibitor (tissue-factor pathway inhibitor-I). A typical human Kunitz domain was chosen as the parental protein since immunogenicity would be minimal due to its human origin and lack of glycosylation which would facilitate the use of phage-display technology. The library was screened against human plasmin, which is a serine protease that participates in the fibrinolytic process. This study synthesized a protease inhibitor exhibiting a high affinity and specificity for plasmin. Small (~ 58 amino acid residues), stable Kunitz domains, which lack glycosylation, and containing nearly human sequences were selected and determined to have high affinity and specificity towards plasmin. The same phage-display library and screening methodology has been used to select high affinity and high specificity ligands for human plasma kallikrein and human thrombin. Markland demonstrated that certain constraints may be imposed upon primary and tertiary structures to increase specificity relative to more simple linear peptide ligands directed towards the same target. For example, a phage-display library was constructed that displayed an 18 amino acid residue peptide containing two fixed cysteine residues to allow disulfide bond formation. In addition, several variable residue positions between and adjacent to the two cysteine residues were included in the peptide sequence. This library was screened against streptavidin and an anti- β -endorphin monoclonal antibody. The screening yielded phage displaying disulfide-constrained microproteins. The selected phage clones required a disulfide bond for the high affinity binding to both target proteins. Other core peptide motifs have resulted in phage-display libraries displaying protease inhibitory domains derived from wild-type bovine pancreatic trypsin inhibitor. In one case, Ladner selected a ligand which was an inhibitor of human neutrophil elastase that had a 3.6 million-fold higher affinity than that for the parental protein and was reported to exceed the highest affinity cited for any human neutrophil elastase inhibitor by 50-fold.

Wholly synthetic combinatorial libraries typically use a robotic assembly of structures. The robotic equipment used to generate orders of structural permutations essentially consists of a miniaturized chemical factory. These multifunction automated work stations perform sequences of sample mixing, thermostatic reactions, volume reduction and purification of the reaction masses. The identity of individual reaction masses is catalogued. Identification of the newly created chemical structures is deduced from automated combinations of liquid chromatography and mass spectrometry. Libraries having 10^3 to 10^4 distinct members have been synthesized and

characterized in this way. The screening of wholly synthetic libraries is laborious due to the need to putatively identify ligand/target complexes and subsequently to test the ligand structure in an immobilized state. In summary, a chief disadvantage of these libraries is the many order fewer library members that can be generated using the current robotic methods. Another disadvantage is cumbersome information acquisition and management associated with both the characterization of the ligand structure and target affinity. Unlike phage display, the primary molecular structure is not encoded and coupled to the wholly synthetic ligand as enabled by DNA of the phage particle. However, the diversity of chemically robust structures that can be produced from wholly synthetic molecules is an important advantage. In addition, rational design models can greatly decrease the number of permutations necessary from the initial discovery of ligands having lower affinity to the design of high affinity ligand candidates based upon initially discovered, ligand structural motifs. If combined with rapid and sophisticated assay screening methods, combinatorial methodologies provide an efficient process for the development of novel drug leads and affinity ligands. Future improvements in the efficiency of screening combinatorial ligands will likely be made using automated chemical sensor technology.

Affinity peptide ligands can be made using solid-phase chemistry. Houghten showed that the solid-phase-linked chemistries have advantages of separation/wash cycling between reaction sequences as well as being able to provide information about the base structure of the candidate ligands. Independent studies by Pingali and Fassina have demonstrated the use of affinity peptide ligands generated from solid-phase peptide synthesis. Pingali produced an affinity peptide that bound human fibrinogen and a peptide of chromochrome c containing haem that captured human serum albumin (HSA). The anti-fibrinogen tetrapeptide was made using standard Fmoc (*N*-fluorenylmethoxycarbonyl) chemistry. The affinity matrix made from this peptide was highly specific as purified fibrinogen was obtained directly from crude human plasma. Frontal analysis determined that the dynamic binding capacity of the antifibrinogen column was 10.2 mg fibrinogen per millilitre of gel. Similarly, by frontal analysis, an HSA-affinity peptide column was found to have a dynamic binding capacity of 19 mg HSA per millilitre of gel. Fassina used a core motif consisting of a small branched-chain peptide to discover a protein A mimetic affinity ligand. This peptide recognized the Fc fragment of immunoglobulin G from rabbit, goat, sheep and mouse and provided a one-step isolation method for

highly purified immunoglobulin G directly from crude sera. Frontal analysis determined that the dynamic binding capacity was 2 mg rabbit immunoglobulin per millilitre of gel. The peptide also exhibited stability towards sanitization reagents such as 0.1 mol L⁻¹ sodium hydroxide and ethanol. Both of the above-mentioned studies show that peptide-based affinity columns derived from standard solid-phase peptide synthesis can provide a viable alternative to the use of immunoaffinity chromatography.

Molecular modelling is used to deduce likely interactions between the target and affinity ligand, and is frequently used as a basis for further rational design of both biosynthetic and wholly synthetic combinatorial libraries. Once certain nominal affinity motifs have been identified from initial ligand screening, rational design has been used to enhance affinity by creating permutations which build upon structural motifs having lower affinity for the target species. In addition, recent studies have been conducted which attempt to develop 'peptidomimetic' structural compounds, such as aminimides, which have core structures similar to that of peptides, but with improved characteristics. Aminimides are much more chemically stable, have enhanced solubility characteristics and are resistant to enzymatic degradation. Ringe formulated a method for structure-based design involving aminimides in which complete binding surfaces of the targets are mapped. Combinatorial chemistry is then used to identify and improve structural specifications in lead candidates targeted at the corresponding binding sites. Ringe developed a peptidomimetic aminide inhibitor or porcine pancreatic elastase based upon crystal structures of an aminimide analogue.

Affinity dyes are another class of wholly synthetic affinity ligands which are not derived from combinatorial libraries. Reactive synthetic textile dyes are resistant to chemical and biological degradation and can bind selectively and reversibly to a wide range of enzymes and proteins. These ligands evolved from ligands which were first classified as enzyme co-factor mimetics. Many of these co-factor mimetics were members of reactive dyes used for staining textiles and paper. Since the mid-1950s, these reactive textile dyes have been used in the affinity purification of proteins. The use of commercial textile dyes as ligands in the large scale processing of diagnostic, therapeutic and genetically engineered proteins is documented throughout the literature. Since that time, many variations of original dye ligand structures, such as reactive Cibacron Blue, have been synthesized. These new structure-function motifs are no longer considered a simple co-factor mimetic relationship as was recognized between nicotinamide

and Cibacron Blue. Cibacron Blue F3G-A, the most thoroughly studied dye ligand, binds with a variety of proteins such as adenine coenzyme-dependent oxidoreductases, phosphokinases, hydrolases, transferases, nucleases, polymerases, synthetases, lyases, decarboxylases, in addition to glycolytic enzymes and plasma proteins. Lowe has shown that the triazine dye structure binds to clefts of proteins which have no known co-factor binding domains, but have much more subtle, yet specific interactions with triazine dye derivatives. Molecular modelling has also improved the rational affinity design of triazine derivatives through the addition of various chemical moieties to the core triazine structure. Lowe demonstrated the use of computer-aided molecular modelling and design in the development of structurally modified biomimetic dyes based on Cibacron Blue F3G-A and Procion Blue MX-R. A dye ligand was engineered specifically for the capture of horse liver alcohol dehydrogenase.

There are several advantages to the purification of pharmaceutical products using synthetic affinity ligands. A major advantage is that they are not derived from biological sources. Therefore they impart less of a product contamination risk. Hence, regulatory issues concerning the presence of unknown contamination and infectious agents in the final product are circumvented. Other major advantages of these ligands include: lower manufacturing cost; they can be readily immobilized under a wide variety of coupling chemistries to an extensive range of commercially available supports; they can be modified to enhance specificity or stability; and they are more stable and less susceptible towards denaturation. In addition, ligands derived from combinatorial libraries may contain a diversity of novel molecular structures such as organically derived or non-natural amino acid residues such as L-amino acids (D-optical isomers). Well-characterized affinity ligands may ultimately dictate decreased final product costs associated with less expensive process costs (i.e. more robust affinity matrices and less expensive ligands) and higher throughput due to a decrease in number of required chromatographic steps (i.e. decreased buffer usage). Affinity separation of pathogens may be better, enabled by the increased accessibility of small ligands to subtle, yet conserved domains of viruses.

Installation of Affinity Ligands

The covalent installation of the affinity ligand into a chromatographic or membrane-based matrix can profoundly affect the ligand/target binding efficiency. Matrix coupling chemistries usually covalently attach ligands through highly reactive groups such as α -

amino groups. Common activation methods for polysaccharide matrices are cyanogen bromide, divinylsulfone, epoxy, organic sulfonyl chlorides, carbonyl diimidazole, and *N*-hydroxysuccinimide. Polyacrylamide matrices are commonly activated by using glutaraldehyde or hydrazine. Isothiocyanate and γ -glycidoxypropylsilane activation methods are commonly used for silica-based matrices.

Ligands which contain amino acids can be coupled through the ϵ -amino group of lysine, carboxyl groups of aspartate and glutamate, and the phenolic group of tyrosine. Chemistries which randomly couple these residues also result in random orientation and spacing of the immobilized ligand. Some of the most thorough studies of ligand coupling chemistries have been done with proteins, especially antibodies. For example, Velander demonstrated that antibodies used as affinity ligands exhibit best performance characteristics when the binding conformation of the antibody is protected during covalent coupling to the adsorbent phase. A conformationally related effect is the orientation of the immobilized ligand. The use of orientated immobilization methods for antibodies is also applicable to synthetic and biosynthetic affinity ligands that have asymmetric structure due to the presence of both target binding and nonbinding domains. The nonbinding domain is best used for covalent coupling. Coupling of ligands to the support matrix through reactive moieties present within the binding domain can be detrimental from both orientation and non-native conformational effects acting upon the ligand. However, masking or shielding of the binding domain prior to immobilization can be employed to circumvent these effects. Velander used synthetic antigens consisting of water-soluble adducts of poly(2-methyloxazoline) polymers and a synthetic peptide epitope for the masking of monoclonal antibody during immobilization. The mask was then removed from the immobilized antibody. A loss of as much as 50% of the theoretical binding capacity of an immobilized antibody was attributed to orientation effects based upon anti-Fc and anti-Fab probing of immunosorbents made using masked and unmasked antibodies.

Activated matrices which preferentially couple through specific functional groups on ligands can aid in the site-directed, orientated immobilization of affinity ligands. For example, Domen developed several activated matrices in which each couple antibodies through different functional groups. Iodoacetyl groups on SulfoLink™ gel are designed to couple through sulfhydryl groups found predominantly in the hinge region of antibodies. CarboLink™ activated gels couple through aldehyde groups. The aldehyde groups on antibodies can be formed by the

oxidation of carbohydrate found primarily in the Fc region of antibodies. The site-directed method of coupling for a bivalent antibody through the oxidized carbohydrate groups using hydrazide chemistry resulted in the theoretical maximum of two antigen molecules for every antibody immobilized. However, Velander and Orthner found some antibodies immobilized on to matrices using hydrazide chemistry, which couple through the carbohydrate groups, produced no significant differences in immunosorbent antigen binding efficiency in comparison to immunosorbents prepared using random coupling chemistries such as cyanogen bromide. These antibodies were found to have carbohydrate in the binding domain.

The covalent attachment of the ligand through spacer arms becomes necessary when the nonbinding domain of the ligand does not offer sufficient molecular spacing between the molecular structure of the adsorbent and the binding domain to enable unencumbered binding of the target. The use of spacer arms is well documented throughout the literature. For example, Cuatrecasas demonstrated that extension of the ligand from the matrix through a hydrocarbon spacer arm can considerably increase ligand/target binding efficiency. Cuatrecasas prepared specific staphylococcal nuclease affinity matrices by immobilizing the competitive inhibitor, pDTP-aminophenyl, using spacer arms of varying length on to agarose and polyacrylamide matrices. Affinity matrices prepared with the ligand attached directly to cyanogen-bromide-activated Sepharose™ yielded a binding capacity of 2 mg nuclease per millilitre of gel whereas affinity matrices, prepared using a ligand attached to the support through a 3,3'-diaminodipropylamine spacer arm, yielded a binding capacity of 10 mg nuclease per millilitre of gel. In addition to ligand proximity to the support surface, the proximal spatial positioning of adjacent ligands within the support influences binding efficiency as well.

A high local ligand density can also encumber target binding between proximally immobilized ligands. Velander also demonstrated that antibodies immobilized with a low, local density gave as much as 50% of theoretical capacity based on a 2:1 target/antibody, molar stoichiometry. Thus, the majority of activity loss associated with the installation of antibodies into matrices can be attributed to local density and orientation effects. As mentioned above, intramatrix transport phenomena can also affect affinity sorbent performance, particularly for large target molecules. Thus, ligands are best installed into domains with rapid target accessibility. However, orientation, spacer arm and local spatial ligand density

effects must be evaluated at any location within the adsorptive matrix as part of the affinity sorbent optimization process.

Future Developments

A diversity of new wholly synthetic affinity ligands will be synthesized by microfluidic devices which will essentially be 'micro-chemical factories on a chip'. Engineering affinity matrices for optimum performance will also include evaluating different immobilization environments to enhance ligand/target interactions. Since many different target binding environments may need to be screened for a given ligand, miniaturized matrices installed on sensors will likely replace the inefficient batch and chromatographic analysis of optimal immobilization environments. Older pharmaceutical processes, such as blood plasma fractionation, will eventually be supplanted by affinity separation processes.

Introduction

Capillary electrophoresis encompasses a number of related separation approaches, some of which are adapted to the requirements of specific applications (Figure 1). They share in common the use of electrolyte solutions as mobile phase, the use of capillary tubes as the separation column, and the use of an electric field to induce sample and mobile phase transport. This allows a similar instrument platform to service all capillary electrophoretic separation techniques with only minor modifications for specific applications. Detection is usually by UV-visible absorption through the fused silica capillary wall, or occasionally by fluorescence, electrochemical or mass spectrometric detection. Contemporary instruments are also highly automated for ease of use and improved control of critical experimental variables.

Classification of capillary electrophoretic techniques according to their usual applications is given in Table 1. These techniques can be considered as

general, sample-type specific, in an early development phase, or of minor importance. Such a broad range of descriptive terms requires further elaboration to indicate how we propose to treat these techniques in this article. Capillary zone electrophoresis (CZE), or simply capillary electrophoresis, and micellar electrokinetic chromatography (MEKC) are widely used and complementary techniques for the separation of ionic and neutral molecules. They are the most important and general in terms of the number of applications and frequency of use. Capillary electrochromatography (CEC) is a relatively new and promising technique with a range of applications similar to liquid chromatography. Since electro-driven flow has been shown to provide both theoretical and practical advantages over pneumatic-driven flow, it has the potential to become a major separation technique. At present, too little is known about the technique to provide a definitive guide to method development, especially as in the future it is likely that new column materials will be developed specifically for capillary electrochromatography with properties different to those currently used. Capillary gel electrophoresis (CGE) is an important technique for the separation of biopolymers but is little used outside of laboratories that perform this type of analysis. Capillary isoelectric focusing (CIEF) is a specialized technique within the field of macromolecule zwitterion separations,

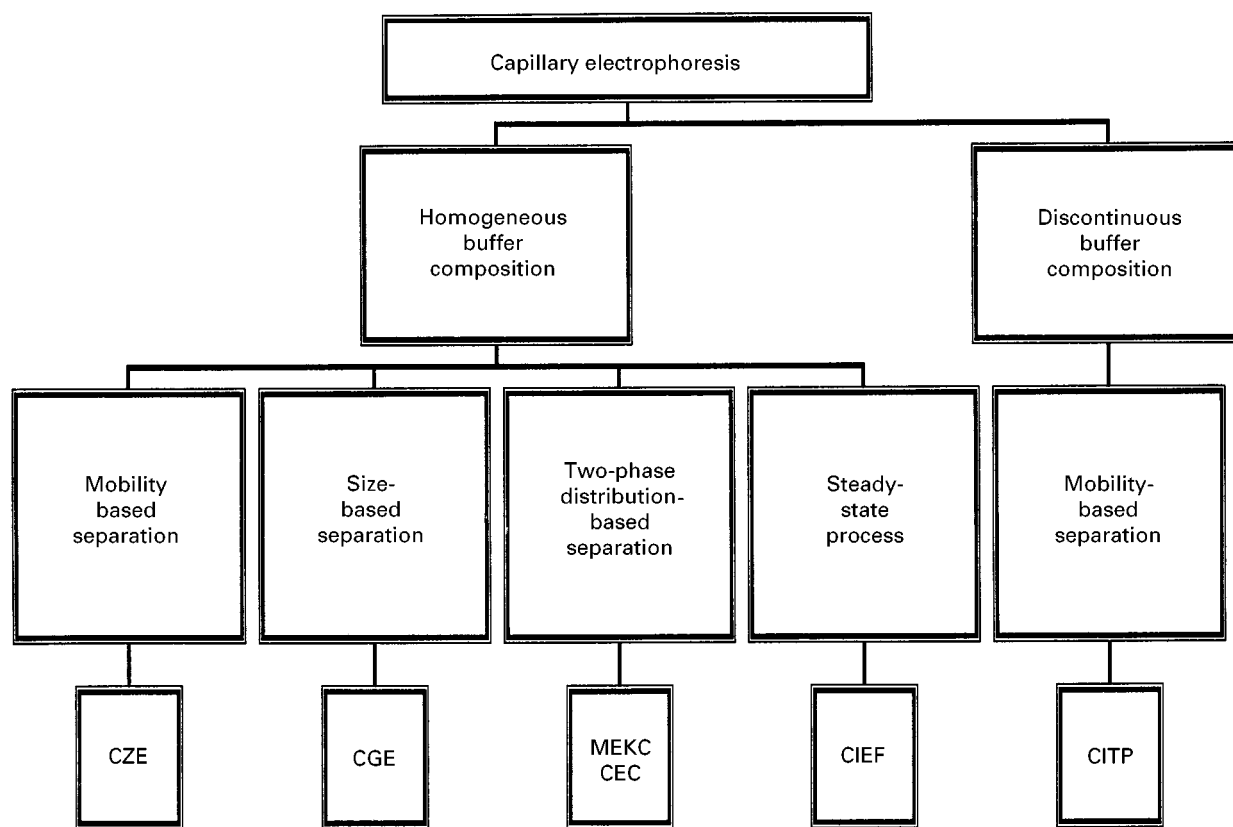

Figure 1 Classification of capillary electrophoretic separation methods based on buffer type and mechanism. CZE = capillary zone electrophoresis; CGE = capillary gel electrophoresis; MEKC = micellar electrokinetic chromatography; CEC = capillary electrochromatography; CIEF = capillary isoelectric focusing; and CITP = capillary isotachopheresis.

largely proteins, requiring special buffers to generate a continuous pH gradient. Capillary isotachopheresis (CITP) is not widely used for separations, it can be rather difficult and tedious to optimize, and yields an integral signal that is different to other separation techniques. Many samples that can be separated by capillary isotachopheresis can also be separated by other electrophoretic techniques more familiar to separation chemists. It is finding increasing use to preconcentrate ions for separation by capillary zone electrophoresis. With this framework in mind we propose to provide general guidelines for method development in capillary zone electrophoresis, micellar electrokinetic chromatography, and gel electrophoresis with only comments and brief instructions applicable to the other capillary electrophoretic techniques.

Sample Suitability

Table 1 provides a general guide to method selection by analogy to established applications. For biopolymers capillary electrophoretic techniques often select themselves, for other compounds the capillary

electrophoretic techniques have to be considered in terms of suitability drawn against other existing chromatographic methods. Reasonable solubility in aqueous solution is required for most separation modes. Non-aqueous capillary electrophoresis is little developed (although promising) and techniques such as micellar electrokinetic chromatography can separate hydrophobic compounds but provide little selectivity. Gas chromatography is usually a better choice for the separation of volatile hydrophobic compounds. High pressure liquid chromatography is often a better choice when low level detection, structural elucidation by mass spectrometry or preparative-scale separations are required. The concentration sensitivity of the capillary electrophoretic techniques using UV-visible absorption detection is limited by the small cross column pathlength and small injection volumes to solutions containing at least $1\text{--}10\ \mu\text{g mL}^{-1}$ and for ease of operation $0.1\ \text{mg mL}^{-1}$ or above is preferred. Various stacking and preconcentration techniques may improve detection limits but these require additional effort and time for optimization that may not be justifiable if another technique is suitable for the separation. Within these

Table 1 Common separation methods using capillary electrophoretic techniques

<i>Technique</i>	<i>Separation mechanism</i>	<i>Applications</i>
Zone electrophoresis	Differences in charge-to-size ratios	Inorganic and organic ions Ionizable compounds Zwitterions Biopolymers
Micellar electrokinetic chromatography	Distribution of neutral and partially ionized compounds between charged micelles and electrolyte solution	Water-soluble neutral compounds Weak acids and bases
Gel electrophoresis	Differences in size and charge (but not size-to-charge ratio) by migration through a gel matrix or entangled polymer network with a range of pore sizes	DNA fragments SDS proteins Macromolecules
Electrochromatography	Distribution between a solid stationary phase and mobile electrolyte solution	Neutral compounds Weak acids and bases Ions
Isoelectric focusing	Differences in isoelectric points in a continuous pH gradient	Proteins Zwitterionic compounds
Isotachopheresis	Differences in electrophoretic mobility of ions sandwiched between two buffers containing ions of greater (leading) and lower (trailing) mobility	Preconcentration of ions

restrictions it is obvious that many sample types and problems can be handled by capillary electrophoretic techniques accounting for its expanding use in analytical chemistry.

Selecting System Variables

Virtually all separations are carried out in fused silica capillary columns 50–100 μm internal diameter and up to 1-m long. Large-bore capillaries provide greater loading capacity and a higher detector response because of the longer pathlength (on-column detection) but generate larger currents and are less efficient at heat dissipation. Small-diameter columns show increased adsorption character due to their larger inner surface area-to-volume ratio but provide more efficient heat dissipation. If detection limits are not a problem, then a small inner diameter column should be used. The choice of capillary length is a compromise between speed (short columns) and separation capacity (long columns). Unless the separation is unusually complicated capillaries should be short (25–50 cm). When a new capillary is put into use or is suspected of being contaminated, a conditioning procedure is required. Washing with a solution of sodium hydroxide, water, and buffer as indicated in Table 2 is normally sufficient. Capillaries with an interior coating are used to alter electroosmotic flow or to minimize analyte ad-

sorption by the capillary wall, particularly for macromolecules. Electroosmotic flow is optimized to obtain useful separations in MEKC and CEC, is often used to improve separations and total sample detection for ions of opposite charge in CZE, but is usually undesirable in CGE, CIEF and CITP. So it is in the later techniques that capillaries with chemically bonded or physically adsorbed coatings are used.

Separations are usually performed with a voltage of 10–30 kV. High voltages provide faster separations with higher efficiency provided that the heat generated is effectively dissipated. A plot of current against applied voltage can be used to optimize operating conditions. The fastest and most efficient separations are obtained at the upper end of the linear portion of the plot. A positive deviation in the plot indicates that the heat removal capacity of the system is being exceeded. Capillary electrophoretic separations are usually performed at or close to room temperature (25°C). Temperature control, however, is important and separation capillaries are thermostated in an air or liquid bath. Thermostating is used to remove heat and to establish a constant temperature. Poor thermostating results in lower efficiency and poor reproducibility of migration times. Temperature is a useful operating variable, which can be used to modify migration times and selectivity, but is generally considered only suitable for fine tuning

Table 2 A guide for selecting initial conditions in capillary electrophoretic separations

Parameter	Setting
Column	Initial experiments use a fused silica capillary 30–50-cm long and 50- or 75- μ m internal diameter. Short columns are appropriate for trial experiments. The complexity of the sample dictates the length. For 2–10 analytes use 35–40 cm; 11–50 analytes 50–60 cm; 50–80 analytes 70–80 cm; and > 80 analytes 90–100 cm. Smaller diameter columns (25 or 50 μ m) provide higher efficiency but lower sample loading capacity.
Initial conditioning	Rinse with 0.1 M sodium hydroxide for 30 min. Flush with water for 15 min followed by the separation buffer for 15 min.
Voltage	Usual range is 10–30 kV. High voltages provide faster separations and greater separation efficiency. The method employed to dissipate heat, the column internal diameter, and buffer type and concentration all affect this decision. Use the highest voltage that does not exceed 100 μ A current as a rough guide. Otherwise plot current against voltage (2.5-kV increments) and operate at a voltage towards the upper portion of the linear plot.
Temperature	Initial experiments use 20–25°C. Selectivity and separation speed varies with temperature, which is optimized to fine-tune a separation (vary from 20 to 60°C in 5°C increments).
Injection	Hydrodynamic (e.g. 3 s at 0.5 p.s.i.) or electrokinetic (2–5 nL)
Detection	Absorption maximum of the analyte of interest, for which the weakest signal is expected because of low concentration or low absorbance. If analyte detection properties are unknown try 200–230 nm.

nearly acceptable separations. Subambient temperatures are not commonly used, as they are less convenient and result in poorer kinetic separation properties.

In general, the sample should be prepared such that the analytes of interest are present in a suitable solution, free from interferences, and at an appropriate concentration for detection. The ionic strength of the sample should be no greater than that of the buffer, with a more or less similar pH to the buffer, and free of matrix problems associated with column wall adsorbing materials and particle matter. For the best peak shapes and resolution the concentration of the injected sample should be about 100 times lower than the concentration of the buffer. Syringe filters for particle removal and ion exchange membrane filtration devices to reduce excessive concentrations of common matrix ions are available. Proteins and similar macromolecules, if not of interest to the analysis, should be precipitated prior to separation to minimize column fouling. Analytes of low water solubility may have to be dissolved in a water-miscible organic solvent or mixture of organic solvent and separation buffer. For other samples it is common practice to dissolve the sample in the run buffer, a diluted solution of the run buffer, or water. Samples are introduced into the separation capillary by hydrodynamic or electrokinetic injection. Both methods provide reproducible injection volumes but sampling bias is associated with electrokinetic injection, which injects increasing amounts of sample components in proportion to their mobility. Hydrodynamic injection is not suitable for CEC and CGE because of the high flow resistance of packed columns.

Capillary Zone Electrophoresis

Once the system variables are set within reasonable ranges the parameters that have most effect on migration times and selectivity are the composition, concentration and pH of the run buffer and the presence of additives, if used, to provide additional selectivity optimization. For a good separation by CZE four features are important: (i) the individual mobilities of the analytes must be different; (ii) the background electrolyte must be homogeneous and the field strength uniform along the column; (iii) neither analytes nor matrix components must interact with the column wall; and (iv) the conductivity of the buffer must substantially exceed the total conductivity of the sample components. Suitable common buffer recipes for a wide pH range are given in Table 3. Additional buffers with their pK_a and anion mobility values are given in Table 4.

Ionic strength and pH greatly affect selectivity and separation time and should be course tuned in initial screening experiments. Low pH is favourable for separating anions (all anions are less mobile) and a high pH is preferred for cation separations. The practical pH range is limited roughly to between 2 and 12. If the pK_a of the sample components is known or can be reasonably estimated, pH optimization should start with a $pH \approx pK_a$. Weak acids and bases change from the neutral form to the fully ionized form over about 4 pH units. In the neutral form their electrophoretic mobility is zero and they all migrate at a fixed velocity due to the electroosmotic flow in common with all neutral species. When totally ionized the ion moves with a constant electrophoretic velocity and may be separated from other

Table 3 Recipes for preparing some common electrophoretic buffers (100 mL of 60 mM buffer)

<i>pH</i>	<i>Buffer system</i>	<i>Acid</i>	<i>Base</i>
	Phosphate	85% Phosphoric acid	Potassium dihydrogenphosphate
2		395.3 mg	349.9 mg
2.5		205.3 mg	574.3 mg
3.0		81.4 mg	720.5 mg
	Acetate	1.0 M Acetic acid	Sodium acetate
3.5		5.67 mL	26.6 mg
4.0		5.08 mL	75.8 mg
4.5		3.81 mL	174.6 mg
5.0		2.13 mL	317.6 mg
5.5		0.89 mL	419.1 mg
	Phosphate	Sodium dihydrogenphosphate (1H ₂ O)	Disodium hydrogenphosphate (2H ₂ O)
6.0		779.2 mg	61.9 mg
6.5		692.8 mg	174.3 mg
7.0		512.2 mg	407.2 mg
7.5		280.7 mg	705.9 mg
8.0		115.5 mg	919.0 mg
	Borate	Boric acid	Disodium tetraborate (10H ₂ O)
8.0		320.9 mg	77.3 mg
8.5		232.7 mg	213.2 mg
9.0		59.3 mg	480.6 mg
	Borate	Disodium tetraborate (10H ₂ O)	0.1 M Sodium hydroxide
9.5		371.0 mg	41.77 mL
10.0		371.0 mg	52.72 mL

ions based on differences in their charge-to-size ratio. When partially ionized the ions migrate with an effective mobility that changes between the two extreme values in a sigmoid fashion as the pH is varied (Figure 2). Ions may be separated in their fully ionized form or partial ionized form as a matter of circumstance; that is, at those conditions that maximizes the difference in charge-to-size ratios. Because changes in mobility tend to be large for partially ionized solutes small pH changes (0.1–0.5 pH units, or smaller for complex mixtures) are used to optimize the separation.

If the pK_a values for a sample are unknown, conduct initial separations in a series of buffers at or near pH 2.5, 4.0, 5.5, 7.0, 8.5 and 10 (see Table 3 for appropriate buffers). To obtain reproducible results over the pH range 4 to 7, careful column conditioning is important. From the plot of the effective mobility against pH identify the most promising pH range for the separation. Optimization then proceeds in smaller changes in pH units as before.

To optimize the buffer concentration initial experiments are performed with a concentration of 30–100 mM for 50- μ m internal diameter columns and 20–50 mM with 75- μ m internal diameter columns. Lower ionic strength buffers are used to obtain faster separations, when selectivity is high, and to separate simple mixtures containing a few

analytes. Higher ionic strength buffers are used for the separation of complex mixtures or to separate analytes with small differences in their electrophoretic mobility. If stacking is used to enhance analyte detectability then the difference in ionic strength between the buffer (high ionic strength) and the sample should be maximized. From Table 4 inorganic buffers are likely to provide better peak shapes for high mobility ions and Good-type (zwitterionic) buffers for low mobility ions. Zwitterionic buffers are useful for many applications where a high concentration and buffering capacity is desirable because of their low specific conductivity, which allows more favourable kinetic separation conditions to be employed.

For difficult separations the selectivity can be further modified by employing secondary chemical equilibria and solvation effects by adding appropriate reagents or solvents to the electrolyte system (Table 5). Increasing the ionic strength of the electrolyte by adding salts such as potassium sulfate modifies the charge and/or conformation of proteins and reduces wall interactions. Metal cations such as Cu^{2+} , Zn^{2+} , Ca^{2+} coordinate to proteins and peptides modifying the net charge. Also, alkanesulfonic acids bind selectively to proteins and peptides through hydrophobic interactions modifying the surface charge as well as reducing wall interactions. Slow

Table 4 Suitable buffers for capillary electrophoresis. Mobility values are at zero ionic strength and 25°C (in $10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$)

Buffer	pK_a	Mobility
Phosphoric acid	2.12 (pK_1)	– 35.10
	7.21 (pK_2)	– 58.30
	12.32 (pK_3)	– 71.50
Malonic acid	2.90 (pK_1)	
	5.70 (pK_2)	
Citric acid	3.13 (pK_1)	– 28.70
	4.76 (pK_2)	– 54.30
	6.40 (pK_3)	– 70.80
Lactic acid	3.85	– 35.80
Hydroxyisobutyric acid	3.97	– 33.50
Glutamic acid	4.38	– 28.90
Acetic acid	4.76	– 42.40
MES [2-(<i>N</i> -morpholine)ethanesulfonic acid]	6.13	– 26.80
MOPS [3-(<i>N</i> -morpholine)propanesulfonic acid]	7.20	– 24.40
MOPSO [2-hydroxy-4-morpholinepropanesulfonic acid]	6.79	– 23.80
ACES [<i>N</i> -2-acetamido-2-aminoethanesulfonic acid]	6.84	– 31.30
Imidazole	7.17	52.00
BES [2-(bis(2-hydroxyethyl)amino)ethanesulfonic acid]	7.16	– 24.00
HEPES [<i>N</i> -2-hydroxyethylpiperazine- <i>N'</i> -2-ethanesulfonic acid]	7.51	– 21.80
TRICINE [<i>N</i> -{tris(hydroxymethyl)methyl}glycine]	8.15	
TRIS [tris(hydroxymethyl)aminoethane]	8.08	29.50
TAPS [3-{tris(hydroxymethyl)methyl}aminopropanesulfonic acid]	8.30	– 25.00

CAPS [3-(Cyclohexylamino)propanesulfonic acid]	10.40	
Diethylammonium	11.40	37.9

adsorption/desorption interactions with the column wall cause peak broadening and tailing and irreversible adsorption leads to modification of the capillary wall. These problems are caused by electrostatic or hydrophobic interactions between macromolecules

**Figure 2** Separation of two hypothetical weak acids as a function of pH by capillary zone electrophoresis.

(usually) and the column wall. Solutions to this problem include using extreme pH buffers, high ionic strength electrolytes, and by using dynamic or chemically bonded wall-coated capillaries. There are no universal solutions and effective methods have to be tailored to the properties of the analyte. Buffer additives are usually used at concentrations of 5–60 mM except for modification of the ionic strength of the electrolyte where much higher concentrations are often required (e.g. 50–250 mM). Urea, which forms hydrogen-bond complexes with proteins and peptides, but is nonionic, is often used at concentrations of 7 M. The separation of metal cations (alkaline earths, transition metals and lanthanides) is difficult because of their similar ionic conductance. In this case complexing agents, such as α -hydroxyisobutyric acid or citrate are required. Since many cations lack a chromophore complexation is an effective method of introducing a chromophore for convenient detection. There is now considerable literature on the separation of anions by capillary electrophoresis. For fast separations it is necessary to reverse the direction of the electro-osmotic flow by adding cationic surfactants below their critical micelle concentration to the buffer

Table 5 Secondary equilibria used to optimize selectivity in capillary electrophoresis

Additives	Function
<i>General considerations</i>	
Inorganic salts	Minimize wall interactions, induce protein conformation changes
Crown ethers	Modify mobility by selective formation of inclusion complexes
Organic solvents	Modify electroosmotic flow, increase solubility of organic ions, modify ion solvation, reduce wall interactions
Urea	Modifies the mobility of proteins by hydrogen-bond complexation
Metal ions	Modify mobility of anions and electroosmotic flow
Alkanesulfonic acids	Modify mobility by ion pair formation, wall adsorption leads to changes in surface properties
Cellulose polymers	Mask active sites on the capillary wall, modify electroosmotic flow
Cationic surfactants	Use to reverse the polarity of the fused silica capillary wall
Organic acids	Modify mobility by ion pair formation
<i>Ion complexation</i>	
Chelate formation (metals)	Polycarboxylic acids (lactate, tartrate, hydroxyisobutyric acid) Ethylene-1,2-diaminetetraacetic acid Dihydroxyazobenzene-5, 5'-disulfonate
Ion pairing	Ionic surfactants (<critical micelle concentration) Cetyltrimethylammonium bromide, tetradecyltrimethylammonium bromide Polyvalent metal cations (Ca^{2+} , Al^{3+} , etc.) CHES and other alkanesulfonic acids, perchlorate
Ion inclusion	Crown ethers (15-crown-6, 18-crown-6, etc.)
<i>Solvent effects</i>	
Organic solvents	Acetonitrile, methanol, 2-propanol, tetrahydrofuran, etc.
Electrolyte	Ionic strength, concentration of the probe (co-ion)

system. The electroosmotic flow and electrophoretic migration now occur in the same direction. For difficult to separate anions normal (counterflow) operation may be the better option at the expense of longer separation times. To reduce peak broadening the mobility of the sample anions should be matched to those of the background electrolyte. For UV-visible detection indirect detection is frequently employed. This requires the addition of a probe (co-ion) of high molar absorption, in low concentration, with the same charge as the analytes. Examples include chromate (most popular), benzoate, salicylate, phthalate, etc.

Micellar Electrokinetic Chromatography

The addition of an ionic surfactant above its critical micelle concentration to the buffer provides an additional separation mechanism based on distribution of the analytes between the micelles and electrolyte. The velocity with which the micelles migrate to the detector is usually different to the velocity of the bulk electrolyte allowing separations based purely on differences in the analyte distribution constants for neutral compounds. For ions differences in both distribution constants and electrophoretic mobility are important. An acceptable separation also requires

favourable kinetic properties (efficiency), provision of an adequate migration window (peak capacity) and a reasonable total separation time. Normally, the experimental conditions are set to establish an acceptable separation time and migration window under conditions where the efficiency is not compromised and the outcome of the experiment controlled by selectivity optimization. Selectivity is influenced largely by the identity of the surfactant and the addition of complexing agents and/or organic solvents to the buffer.

Some common surfactants and their relative solvation properties are summarized in Table 6. Method development usually begins with sodium dodecyl sulfate because of its favourable kinetic and chromatographic properties. (Table 7). Other surfactants are selected based on their complementary properties to sodium dodecyl sulfate using the system constants of the solvation parameter model as a guide (Table 6). For example, sodium cholate (representative of the bile salts) is a stronger hydrogen-bond base and weaker hydrogen-bond acid than sodium dodecyl sulfate. By similar reasoning a working list of surfactants for selectivity optimization would include sodium dodecyl sulfate, sodium cholate, lithium perfluorooctanesulfonate, sodium *N*-dodeconyl-*N*-methyltaurine and tetradecyltrimethylammonium bromide. Table 6 also provides a framework to identify new surfactants

Table 6 Characteristic properties of common surfactants for micellar electrokinetic chromatography

Surfactant	Critical micelle concentration (mM)	Aggregation number	Solvation parameter model system constants*				
			<i>m</i>	<i>r</i>	<i>s</i>	<i>a</i>	<i>b</i>
Sodium dodecyl sulfate	8.2	62	2.99	0.46	− 0.44	− 0.30	− 1.88
Tris(hydroxymethyl)aminoethane dodecyl sulfate			2.56	0.57	− 0.66	− 0.33	− 1.56
Sodium dodecyl sulfonate	9.8	54	2.51	0.51	− 0.70	− 0.14	− 1.51
Sodium cholate	13–15	2–4	2.45	0.63	− 0.47	0	− 2.29
Sodium taurocholate	2.8	4	2.43	0.60	− 0.34	0	− 2.06
Sodium deoxycholate	4–6	4	2.67	0.66	− 0.47	0	− 2.47
Sodium taurodeoxycholate	2–4	8	2.62	0.67	− 0.45	0	− 2.17
Sodium <i>N</i> -dodecanoyl- <i>N</i> -methyltaurine	8.7		3.07	0.72	− 0.50	0.22	− 2.58
Lithium perfluorooctanesulfonate			2.30	− 0.52	0.34	− 0.82	− 0.53
Tetradecyltrimethylammonium bromide	4.4	64	2.82	0.36	− 0.29	0.90	− 2.67
Hexadecyltrimethylammonium bromide	0.026	169	3.40	0.61	− 0.55	0.58	− 3.08
Microemulsion**			3.05	0.28	− 0.69	− 0.06	− 2.81

*The *m* system constant is a measure of the difference in cohesive energy and dispersion interactions for the micelles and electrolyte; the *r* system constant the difference in interactions with lone pair electrons; the *s* system constant the difference in interactions of a dipole type; the *a* and *b* system constants the difference in hydrogen-bond base and hydrogen-bond acid interactions, respectively. The sign of the constant indicates whether the interaction favours distribution to the micelles (positive) or electrolyte system (negative). **Microemulsion consisting of 1.4%wt. sodium dodecyl sulfate, 6.49% wt. butan-1-ol and 0.82%wt. heptane.

with complementary properties to those available at present and to avoid unnecessary experiments with surfactants with different structures but nearly identical selectivity properties.

When selectivity optimization using different surfactant types is exhausted further optimization is achieved by the use of additives (see Table 7). For this purpose the common approaches are the use of mixed

Table 7 Starting conditions for method development in micellar electrokinetic chromatography

Parameter	Setting
Sample	1–2 mg mL ^{−1} dissolved in methanol or water
Column	Fused silica capillary 30–50-cm long with an internal diameter of 50 μm
Initial conditioning	Flush with 0.1 M sodium hydroxide for 3 min and rinse with the run buffer for 5 min. These conditions will have to be varied depending on the previous use (if any) of the column. It is preferable to reserve individual capillaries for each surfactant.
Buffer	20 mM sodium phosphate–sodium tetraborate pH 8 buffer (or see Table 3 for suitable single buffers) containing 50 mM sodium dodecyl sulfate
Voltage	20–25 kV
Temperature	25°C
Injection	50 mbar 1–2 s (hydrodynamic)
Detection	210 nm (or absorption maximum for analyte with lowest absorbance)
<i>Course tuning selectivity</i>	
Surfactant	Choose surfactants of different selectivity (see Table 6) Sodium cholate (72 mM) Sodium <i>N</i> -dodecanoyl- <i>N</i> -methyltaurine (50 mM) Tetradecyltrimethylammonium bromide (50 mM) with reverse polarity Other suitable surfactants
pH	Optimize migration window and separation time (lower pH to extend and raise pH to lower) for neutral compounds. Weak acids and bases may show significant changes in electrophoretic behaviour
Additives	Mixed surfactants formed with neutral and ionic surfactants. For example, Brij 35 (polyoxyethylene[23] dodecyl ether) 1–25 mM Organic solvents methanol, 2-propanol, acetonitrile, tetrahydrofuran 1–25% (v/v) Higher molecular mass solvents of low water solubility 1–5% (v/v) Complexing additives such as α-, β-, γ-cyclodextrins, hydroxypropyl-β-cyclodextrin and heptakis-(2,3,6-tri-O-methyl)-β-cyclodextrin (5–20 mM)
<i>Fine tuning selectivity</i>	
Modify system properties such as column length, temperature, voltage, buffer type and ionic strength.	
Surfactant concentration changes the phase ratio but has little effect on selectivity	

Figure 3 Change in the system constants obtained from the solvation parameter model as a function of the composition of the mixed micelles formed with the neutral surfactant Brij 35 (1–50 mM) and 50 mM sodium dodecyl sulfate. See Table 6. (Reproduced with permission from Poole SK and Poole CF (1997) Variation of selectivity with composition for a mixed-micellar buffer in micellar electrokinetic chromatography. *Journal of High Resolution Chromatography* 20: 174–178.)

surfactant micelles, organic solvents and inclusion complexing agents. A large number of mixed micelles can be employed without any certain prospects of

success. Neutral surfactants such as Brij 35 are often chosen first to adjust selectivity and/or the size of the migration window. **Figure 3** shows an example of the use of Brij 35 to change the selectivity of sodium dodecyl sulfate micelles. The solvation properties of the mixed micelles are not changed radically, even at high concentrations of the neutral surfactant, in agreement with predictions made by the interphase retention model. The main change is the gradual decrease in the hydrogen-bond acidity of the mixed micelles, which should provide a useful change of selectivity for the separation of hydrogen-bond bases. Selectivity modification by addition of organic solvent to the buffer is by no means as useful as in reversed-phase liquid chromatography. At low concentrations modifier effects are small and not strongly dependent on solvent identity, and at higher concentrations they lead to deleterious effects on system efficiency and the separation time. By contrast, the use of complexing additives, such as urea and cyclodextrins has to be considered one of the success stories of MEKC for achieving the separation of isomers, enantiomers, and other difficult to separate compounds capable of forming suitable inclusion complexes. **Figure 4** provides an example of the separation of pharmaceutically important estrogens that were only adequately separated in the system containing the complexing additive. The incorporation of low molecular mass organic solvents and cyclodextrins in the micelles is very low. Their main effect on the distribution properties of the system

Figure 4 Separation of estrogens by MEKC using a 20 mM sodium phosphate-borate pH 8 buffer containing 50 mM sodium dodecyl sulfate (A) and the same buffer containing 20 mM γ -cyclodextrin (B). Separation conditions: capillary 48.5 cm (effective length 40 cm), internal diameter 50 μ m, temperature 25°C, and field strength 20 kV. Compounds: 1 = estriol; 2 = 17 β -estradiol; 3 = 17 α -estradiol; 4 = 17 β -dihydroequilenin; 5 = 17 β -dihydroequilenin; 6 = 17 α -dihydroequilenin; 7 = 17 α -dihydroequilin; 8 = estrone; 9 = equilenin; and 10 = equilin. (Modified from Poole SK and Poole CF (1996) Separation of pharmaceutically important estrogens by micellar electrokinetic chromatography. *Journal of Chromatography A* 749: 247–225, with permission from Elsevier Science.)

is due to changes in the relative solubility of the analytes in the electrolyte.

Capillary Gel Electrophoresis

Capillary gel electrophoresis is used for the separation of macromolecules such as proteins and nucleic acids, whose mass-to-charge ratios do not vary much with size. Separation requires a sieving medium made up of a crosslinked gel or an entangled polymer network. The capillaries are often wall-coated or chemically bonded to minimize electroosmotic flow that tends to destabilize the columns. Columns filled with rigid crosslinked gels, usually polyacrylamide, are characterized by the total amount of monomer and crosslinking agent (%T) and the ratio of crosslinking agent to total amount of monomer and crosslinking agent (%C) used to prepare the column. Larger pore size gels (lower %T) are used for separating DNA sequencing reaction products whereas the narrow-pore media are best for proteins and small oligonucleotides. Entangled polymer networks of linear polyacrylamide, methylcellulose or dextran have the advantage that they can be forced into the capillary as a solution and replaced when needed. Unlike gels, columns are easily prepared in the laboratory and tend to be more robust. Electrokinetic injection is used for sample introduction. The buffer pH is selected such that the analytes of interest are ionized. TRIS/borate and TRIS/phosphate buffers in the pH range 7.5 to 8.5 (50–200 mM) are fairly general conditions. Sometimes urea (7–8 M) or ethylene glycol (1.5–3.0 M) is added to the buffer as a nonionic denaturing or solubilizing agent and EDTA (about 2 mM) to protect against cation interferences. When SDS-proteins are separated sodium dodecyl sulfate (0.1% w/v) is added to the run buffer. For many practical applications of capillary gel electrophoresis the column materials and reagents required can be purchased in kit form.

Capillary Isoelectric Focusing and Isotachopheresis

Capillary isoelectric focusing is used to separate polypeptides based on differences in their isoelectric points (pI) in wall-coated fused silica capillaries to eliminate electroosmotic flow and nonspecific adsorption of the sample with the capillary wall. The capillary is filled with the sample and a mixture of ampholytes capable of producing a pH gradient that covers the pI values of the proteins. Ampholytes are a mixture of hundreds to thousands of amphoteric compounds, generated by the random addition of acrylic acid to a mixture of linear and branched

oligoamines, providing pI values are fairly well distributed along the pH scale from 3 to 10. In practice about 94% of proteins can be separated in the pH range 3–8.5. This allows a single capillary to be used for hundreds of separations by minimizing alteration to the capillary wall coating. When a voltage is applied (e.g. 15 kV for 4 min) the sample components focus into narrow zones according to their pI values. The zones are then mobilized by hydraulic, electroosmotic or ion addition (by adding 80 mM sodium chloride to either the source or destination vial and applying an electric field) to move them past the detector. The destination vial contains a buffer (catholyte) at a pH higher than the pI of the most basic ampholyte (40 mM sodium hydroxide) and the source vial contains a buffer (anolyte) at a pH lower than the pI of the most acidic ampholyte (20 mM phosphoric acid). To avoid protein precipitation in the focused zones a surfactant or urea can be added to the buffer, the sample diluted, or gel-filled capillaries can be used.

In capillary isotachopheresis sample ions are separated by differences in their mobility in a heterogeneous buffer system created by sandwiching the sample between a leading and terminating buffer with different and specified compositions. It is general practice to separate mixtures in the constant current mode using chemically bonded or dynamically coated capillaries to eliminate electroosmotic flow. As well as fused silica capillaries of standard dimensions wide-bore Teflon (0.5–0.8 mm) tubes have been used in purpose-built apparatus for isotachopheresis. Before commencing the separation both the capillary and destination buffer vial is filled with the leading electrolyte (assuming suppression of the electroosmotic flow). The leading electrolyte ion must have a higher mobility than any of the analytes to be separated and the counterion must be able to set the pH for the separation by ensuring sufficient (but generally not complete) dissociation of weak acids and bases in their own zones. Either sample cations or anions can be determined in the separation but not both simultaneously. The terminating electrolyte is placed in the source vial and should have a lower mobility than any of the analyte ions. Recommendations for buffer selection and operating conditions are summarized in Table 8. If solubility is a problem nonionic or zwitterionic surfactants or urea can be added to both the leading electrolyte and the sample. When fused silica capillaries are used hydroxypropylmethylcellulose, polyethylene glycol or polyvinyl alcohol can be added to the buffers to suppress electroosmotic flow through dynamic coating of the column wall. Detection of

Table 8 Composition of some common capillary isotachopheresis buffers*

Property	pH				
	2.0	3.3	4.5	6.0	8.8

the separated zones is usually by conductivity or UV-visible absorption. The method has high peak capacity since separated zone boundaries are sharp and close to each other to maintain continuity of the current. When the experimental conditions are correct a steady state is reached in which all zones are migrating at the same speed and the detector output is a series of steps, the length of which corresponds to the concentration of the ion. At first sight the data presentation may be confusing and this combined with the complex method development has suppressed interest in capillary isotachopheresis in favour of other chromatographic methods. The compelling advantage of isotachopheresis is its ability to trace enriched dilute samples, by 100-fold or more, and as a preconcentration or pre-separation technique for capillary zone electrophoresis it is enjoying something of a renaissance.

Conclusions

The capillary electrophoretic methods are sufficiently established to ensure their continued laboratory use but not so mature that significant developments are unexpected in the near future. These developments are likely to be application driven and will impact on the method development process. New systems for separation of biopolymers using gels and

entangled polymers, a wider range of surfactants for selectivity optimization in micellar electrokinetic chromatography, and tailor-made sorbents for selectivity optimization and control of electroosmotic flow in electrochromatography are just some expected improvements. Better models for predicting sample migration should aid computer-aided method development strategies and experimental design approaches for multiparameter optimization of complex mixtures should grow in popularity.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN EXTRACTION

J. R. Dean, University of Northumbria at Newcastle, Newcastle upon Tyne, UK

Copyright © 2000 Academic Press

Introduction

Samples for extraction can be broadly categorized as solid, liquid or gaseous matrices. It is obvious that the different methods of extraction of analytes from

these matrices will also vary. This guide provides an overview of the different approaches for extraction of analytes from these different matrices.

It is important to consider that extraction is only one part of the sample preparation protocol. Other steps are highlighted in Figure 1. A typical solid sample is most likely to be heterogeneous. This is a problem in the analysis, if appropriate steps have not been taken to remove a representative sample using a statistical approach. Failure to do so can make any subsequent extraction and analysis results meaningless.

Also of relevance to any subsequent extraction and analysis is whether the sample has been stored (and preserved, if necessary) in the appropriate manner to prevent losses of the analyte due to degradation and/or adsorption. It is necessary to consider, in the

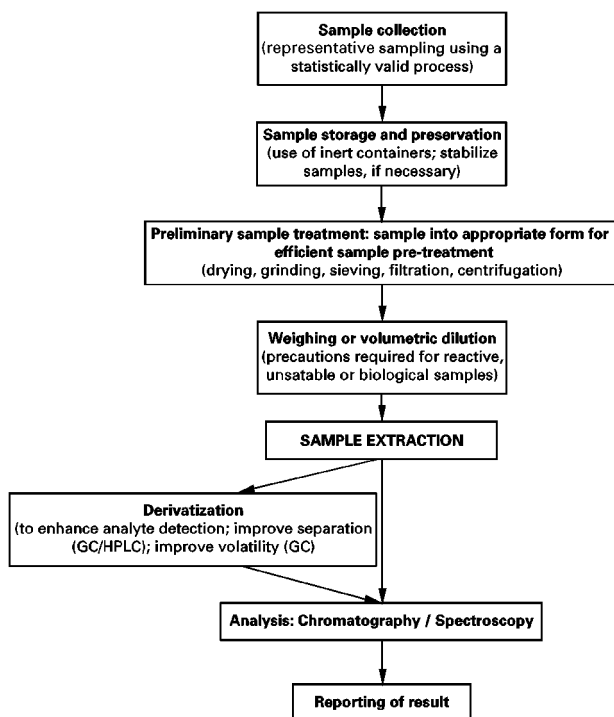

Figure 1 Sample preparation protocol.

Figure 2 Extraction of analytes from solid matrices.

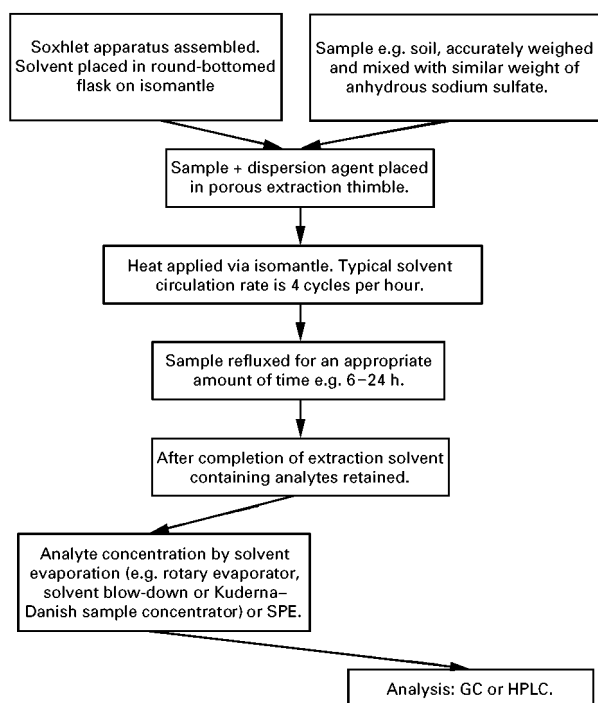

Figure 3 Soxhlet extraction.

case of a soil sample, whether it should be dried (volatile analytes may be lost) or extracted in the unadulterated state. If possible, drying is favoured, as the subsequent matrix can be ground and sieved to increase its surface area (smaller particle size).

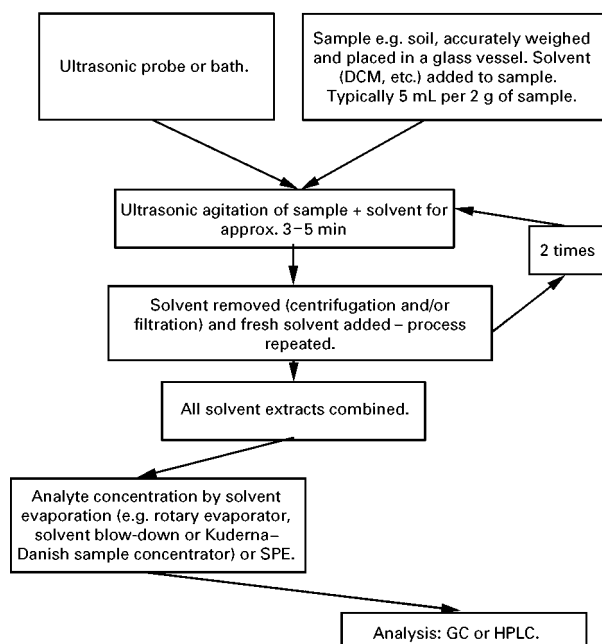

Figure 4 Ultrasonic extraction.

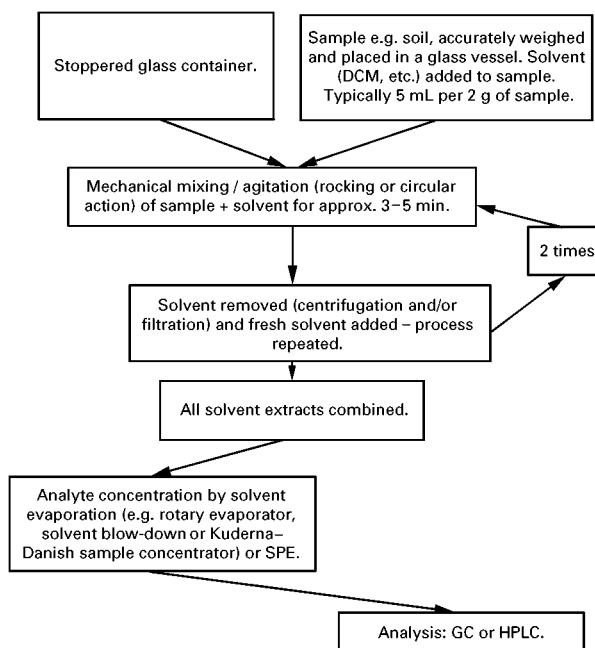

Figure 5 Shake-flask extraction.

Solid Matrices

Extraction of analytes from solid matrices can be classified according to the scheme shown in Figure 2. The main extraction techniques are Soxhlet extraction, soxtec extraction, supercritical fluid extraction

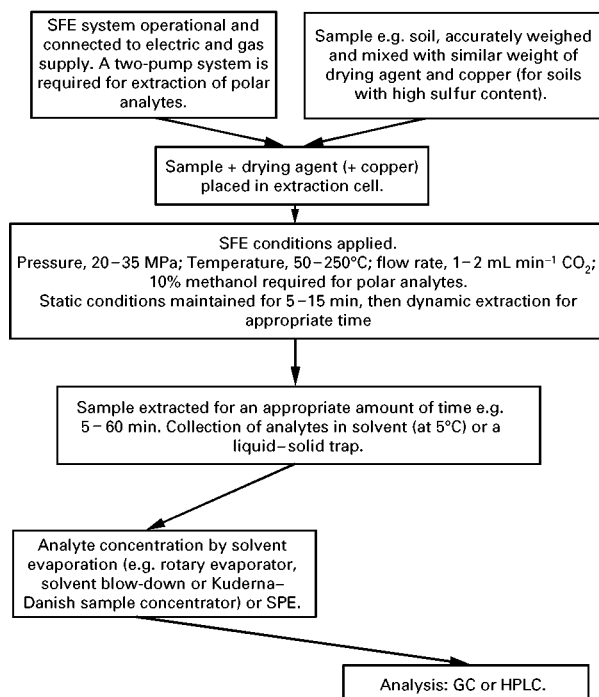

Figure 6 Supercritical fluid extraction.

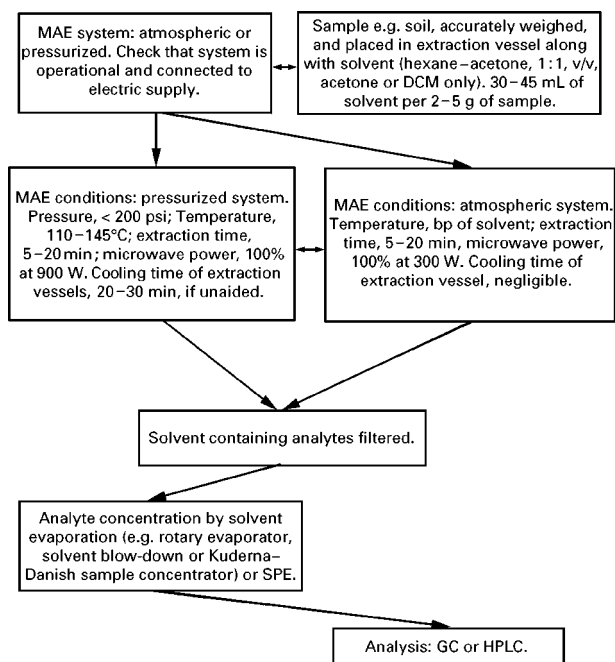

Figure 7 Microwave-assisted extraction.

(SFE), pressurized microwave-assisted extraction (pMAE), atmospheric microwave-assisted extraction (aMAE), pressurized fluid extraction (PFE) or accelerated solvent extraction (ASE), ultrasonic ex-

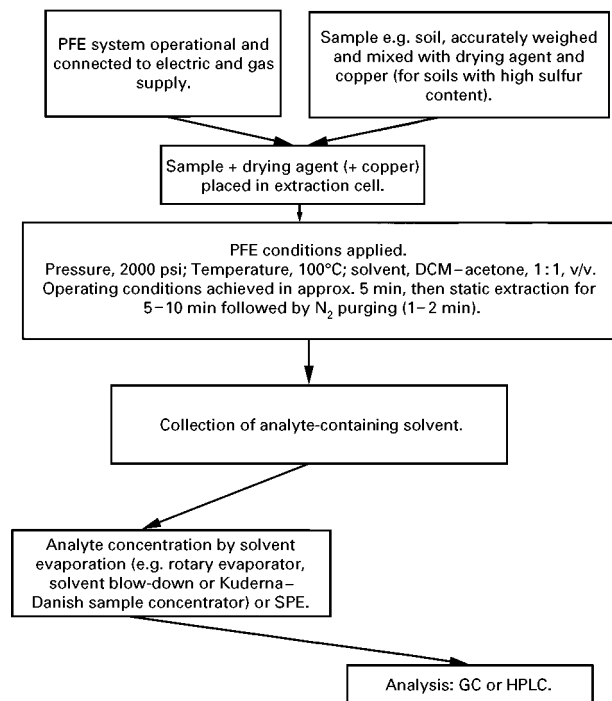

Figure 8 Pressurized fluid extraction (or accelerated solvent extraction).

traction, shake-flask extraction and matrix solid phase dispersion (MSPD). Method development approaches for each extraction technique are shown in Figures 3–10.

Liquid Matrices

Liquid extraction approaches are essentially centred around methods of preconcentration. Typically, this involves the use of sorbent and/or an organic solvent. The choice of solvent/organic solvent depending upon the nature of the analyte, e.g. polar/nonpolar. The main extraction approaches are liquid–liquid

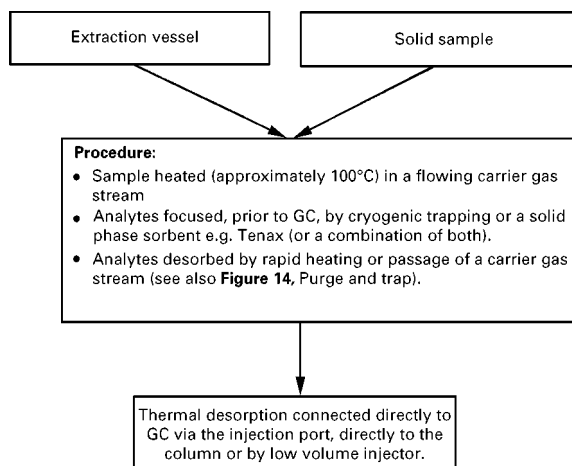

Figure 10 Thermal desorption.

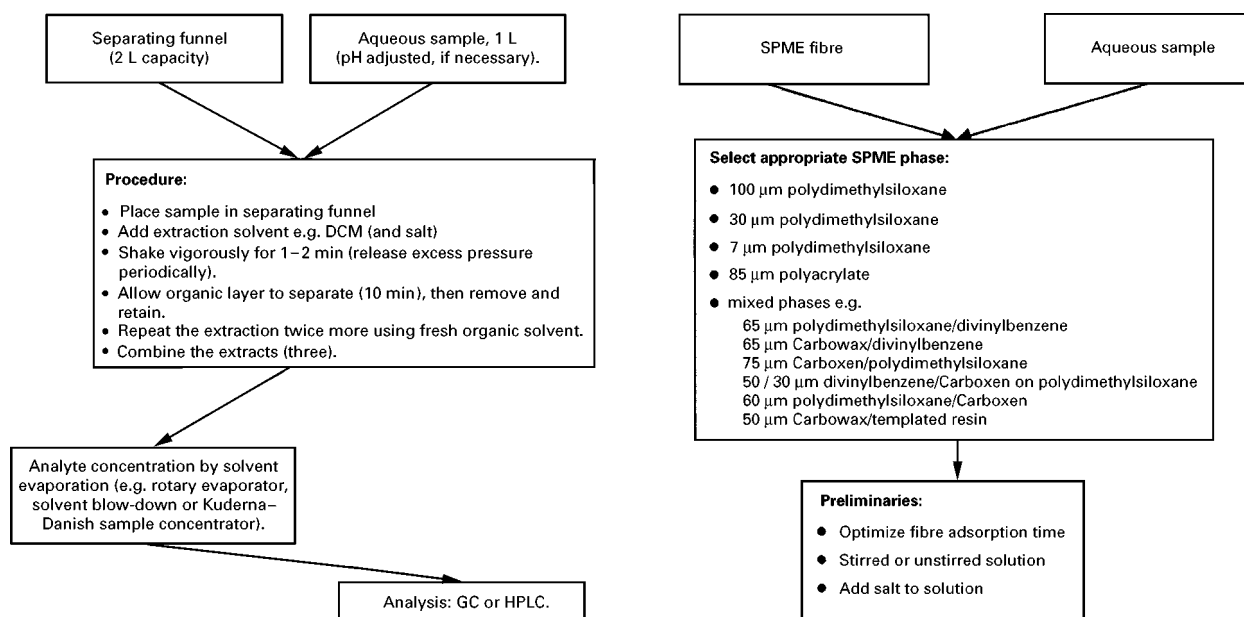

Figure 11 Separating funnel liquid–liquid extraction.

extraction (LLE), solid-phase extraction (SPE) and solid-phase microextraction (SPME). A guide to method development for each extraction technique is shown in Figures 11–14.

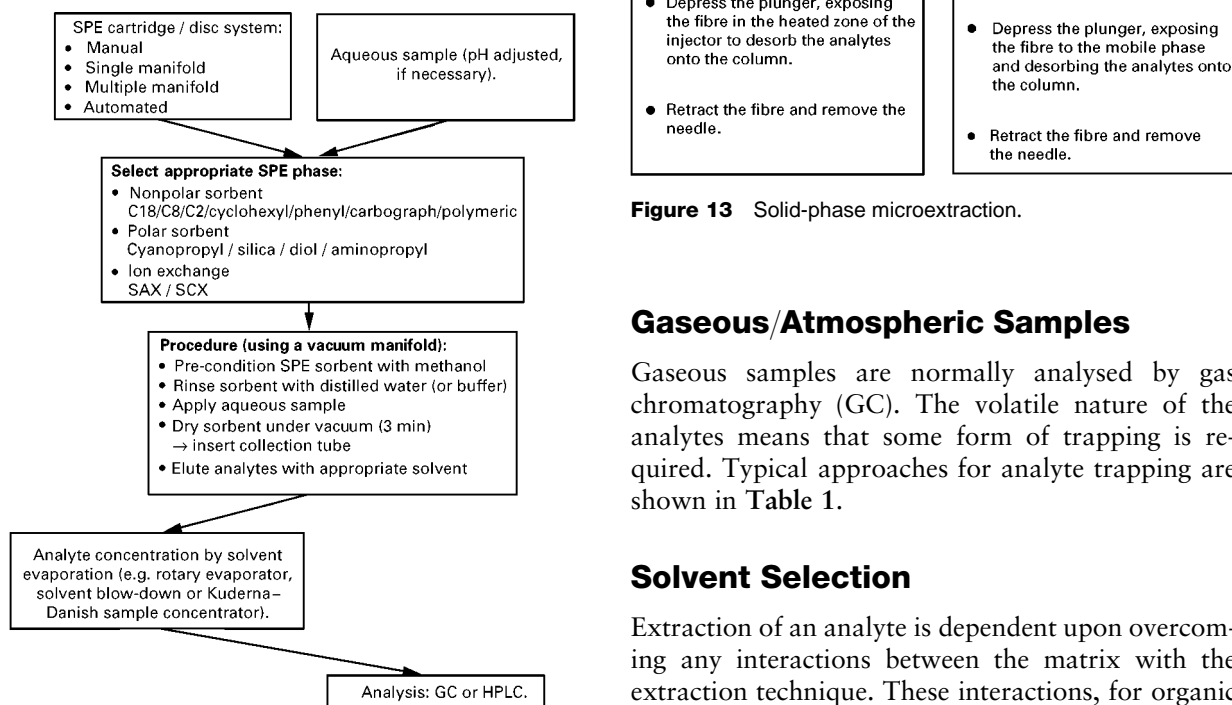

Figure 12 Solid-phase extraction.

Figure 13 Solid-phase microextraction.

Gaseous/Atmospheric Samples

Gaseous samples are normally analysed by gas chromatography (GC). The volatile nature of the analytes means that some form of trapping is required. Typical approaches for analyte trapping are shown in Table 1.

Solvent Selection

Extraction of an analyte is dependent upon overcoming any interactions between the matrix with the extraction technique. These interactions, for organic molecules, are predominantly based on weak forces of attraction between the analyte and the matrix, e.g.

Table 1 Common approaches for gaseous samples

Technique	Comments
Solid phase trapping	Gaseous sample passed through a sorbent, e.g. Tenax, activated charcoal, etc. Trapped analytes are eluted with a suitable solvent.
Liquid trapping	Gaseous sample is bubbled through a suitable trapping solvent. To improve trapping efficiency it is important to minimize the flow rate and/or lower the temperature. The use of multiple traps or impingers may be necessary.
Headspace sampling	Solid or liquid sample placed in a sealed glass vial until equilibrium is reached. Volatile analytes sampled from the headspace using a gas-tight syringe or solid-phase microextraction.
Purge and trap	See Figure 14.
Solid-phase microextraction	See Figure 14 and Headspace sampling, above.

DDT	23.46	9.75	3.13	25.60

Van der Waal's, hydrogen bonding, etc. While the choice of extraction technique is important, often for economic and environmental concerns, its physical/chemical properties are largely influenced by the choice of solvent (in most cases). This is not to say that the effects of heat, pressure, agitation and sorbent are negligible, but that these on their own are largely unimportant without the presence of an organic solvent and that the choice of solvent is critical. Apart from general rule of thumb guidelines for sol-

vent selection, i.e. like extracts such as a nonpolar analyte can be extracted by a nonpolar solvent, little attempt has been made to offer a scientific approach.

The solvent prediction scheme used is based on the Hildebrand solubility parameter (δ_t). The solubility parameter is a measure of the internal energy of cohesion in the solvent/solute. Solvents with similar solubility parameter form mixtures, hence an analyte and a solvent that have similar solubility parameters, should also form mixtures.

Figure 14 Purge and trap.

δ_t is defined as the square root of the cohesive energy density or:

$$\delta_t = (\Delta E_v / V)^{1/2} \quad [1]$$

where δ_t = total Hildebrand solubility parameter, ΔE_v = energy of vaporization at a given temperature and V = molar volume of the molecule.

Hansen (1967) took this work further and assumed that the total cohesive energy is a linear addition of

Figure 15 Comparison of calculated solvent and analyte fractional parameters.

Table 4 Pressurized fluid extraction of DDT from contaminated soil followed by GC-MSD quantitation, $n = 6^a$

Solvent	Mean $\mu\text{g g}^{-1}$	SD
Methanol	89	10.1
Acetone	163	7.4
Dichloromethane	220	13.9
Acetonitrile	65	2.9
Iso-Hexane	120	4.4

^aExtraction conditions: sample size 2 g; temperature, 100°C; pressure 2000 psi; static extraction time 10 min; one static/flush cycle.

three components: δ_h , hydrogen bonding ability contribution; δ_d , dispersion co-efficient contribution; and, δ_p , polarity contribution. They are linked by the following equation:

$$\delta_t^2 = \delta_h^2 + \delta_p^2 + \delta_d^2 \quad [2]$$

The individual components of δ_t can be determined using a group contribution additive method. The data available allows each group's contribution to polarity, dispersion and hydrogen bonding (F_p , F_d , and U_h , respectively) to be calculated using the following equations δ_p , δ_h , and δ_d :

$$\delta_d = (z \Sigma F_d) / V \quad [3]$$

$$\delta_p = (z \Sigma F_p) / V \quad [4]$$

$$\delta_p = (z \Sigma F_p^2)^{1/2} / V \quad [5]$$

$$\delta_h = ((z \Sigma U_h) / V)^{1/2} \quad [6]$$

For molecules with more than one polar group present, then eqn [5] must be used instead of eqn [4] to take into account the interactions between the polar groups.

An example calculation of the individual components of the solubility parameter for a solvent (methanol) and an analyte (1,1,1-trichloro-2,2-bis(p-chlorophenyl)ethane (DDT)) are shown in Table 2. The individual Hansen parameters for a range of solvents and an analyte (DDT) are shown in Table 3. As an example, the calculated total Hildebrand solubility parameter, δ_t , for methanol (28.3 MPa^{1/2}) compared favourably with the literature value of 29.6 MPa^{1/2}.

In order to normalize the data, fractional parameters of the Hildebrand solubility parameter can be calculated and plotted on a triangular graph in order to give a visual representation of the extent of contribution from the three components (polarity,

Box 1 Soxhlet extraction of polycyclic aromatic hydrocarbons from contaminated soil.**Extraction conditions**

Sample size: 10 g plus 10 g anhydrous sodium sulfate

Solvent: 150 mL dichloromethane

Extraction time: 24 h

Comments: sample heated using an isomantle. Typically, refluxing of solvent occurs at the rate of 4 h^{-1} .

Extracts were concentrated to 10 mL using rotary evaporator and then diluted twofold before addition of the internal standards.

Analysis of extracts by GC

Separation and identification of individual PAHs was done on a HP 5890 series II + GC fitted with a HP 5972A mass spectrometer. A $30 \text{ m} \times 0.25 \text{ mm i.d.} \times 0.25 \mu\text{m}$ film thickness DB-5 capillary column was used with temperature programming from an initial temperature held at 85°C for 2 min before commencing a 6°C min^{-1} to 300°C , with a final time of 7 min. The split/splitless injector was held at 300°C and operated in splitless mode with the split value closed for 1 min following sample injection. The split flow was set at 40 mL min^{-1} , and the mass spectrometer transfer line was maintained at 270°C . Electron impact ionization at 70 eV with an electron multiplier voltage set at 1500 V was used while operating in single-ion monitoring (SIM) mode.

Typical results: Saim N, Dean JR, Abdullah MP and Zakaria Z (1997) *Journal of Chromatography* 791A: 361.

dispersion and hydrogen bonding). A plot of selected solvents and DDT is shown in Figure 15. Using this plot, it can be seen that dichloromethane (DCM) is predicted to be the optimum solvent for extraction of DDT. Table 4 shows results for the extraction of DDT contaminated soil for selected solvents using accelerated solvent extraction (ASE). It is clearly shown that DCM gives the highest recovery of DDT. Similarly, it is also predicted and confirmed that both isohexane and acetone would remove significantly more of the DDT than methanol and acetonitrile. Work is on-going to identify whether the model can be applied to other systems.

Selected Examples of Extraction of Analytes from Environmental Matrices

In order to provide specific details on particular extraction techniques selected examples are provided from the author's own laboratory. In particular, the following techniques are covered: **Box 1**, Soxhlet extraction of polyaromatic hydrocarbons (PAHs) from contaminated soil; **Box 2**, shake flask extraction of four phenols from soil; **Box 3**, SFE of OCPs from soil and Celite; **Box 4**, pressurized microwave-assisted extraction of PAHs from soil; **Box 5**, atmospheric microwave-assisted extraction of PAHs from

Box 2 Shake flask extraction of phenols from soil**Extraction conditions**

Sample size: 1 g

Solvent: 50 mL methanol–water (60–40% v/v)

Extraction time: 30 min

Comments: Sample and solvent placed in a 100 mL screw-capped bottle and extracted on a rotating disc Warburg mixer. Resultant sample/solvent was filtered under vacuum. Sample extracted filtered through a 0.45 μm membrane Acrodisc prior to analysis.

Analysis by HPLC

Separation and quantification was achieved using a 25 cm \times 4.6 mm i.d. ODS2 column with UV detection at 275 nm. The mobile phase was operated under isocratic conditions acetonitrile–H₂O–acetic acid (40 + 59 + 1) at a flow rate of 1 mL min⁻¹. A 20 μL Rheodyne injection loop was used to introduce samples and standards on to the column (30°C).

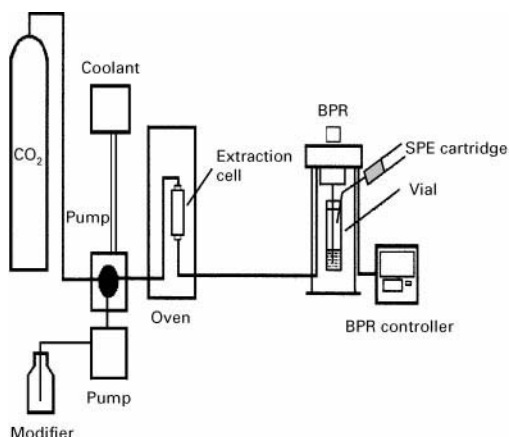

Typical results: Hancock P and Dean JR (1997) *Analytical Communications* 34: 377.

soil; **Box 6**, pressurized fluid extraction of DDT, 1,1-dichloro-2,2-bis(p-chlorophenyl)ethane (DDD) and 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene (DDE) from soil; **Box 7**, liquid–liquid extraction of PAHs from water; **Box 8**, SPE of phenols from water; **Box 9**, solid-phase microextraction of benzene,

toluene, ethyl benzene and xylene (BTEX) from water; and, **Box 10**, purge and trap of BTEX from water.

Further details on the theoretical and technical aspects of these and other extraction techniques can be found in the relevant entries in the Encyclopedia.

Box 3 Supercritical fluid extraction of organochlorine pesticides from soil and Celite**Extraction conditions**

Sample size: 1 g

SFE conditions: pressure, 250 kg cm⁻²; temperature, 50°C; static extraction time, 15 min followed by 40 min dynamic extraction time; and a flow rate of liquid CO₂, 2 mL min⁻¹.

Comments: Extracts collected in a vial containing 3–4 mL DCM. Escaping CO₂ and analytes vented through a C18 SPE cartridge which was back-flushed with 1–2 mL methanol after each extraction.

Analysis by GC

Separation and identification of individual OCPs was done on a HP 5890 series II + GC fitted with a HP 5972A mass spectrometer. A 30 m × 0.25 mm i.d. × 0.25 μm film thickness DB-5 capillary column was used with temperature programming from an initial temperature held at 85°C for 0.75 min before commencing a 16°C min⁻¹ to 285°C, with a final time of 2 min. The split/splitless injector was held at 280°C and operated in splitless mode with the split valve closed for 1 min following sample injection. The split flow was set at 40 mL min⁻¹, and the mass spectrometer transfer line was maintained at 290°C. Electron impact ionization at 70 eV with an electron multiplier voltage set at 1500 V was used while operating in single-ion monitoring (SIM) mode.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN FLOTATION

E. Woodburn, UMIST, Manchester, UK

Copyright © 2000 Academic Press

General

This article is designed to develop methods for an interested non-specialist, by showing how they can be used as a basis for a Chemical Engineering Unit Operations course.

Flotation is practised extensively in industry. The technique requires a detailed knowledge in physical metallurgy, the physical chemistry of surfaces, a competence both in mathematics and practical hydrodynamics.

The operation is based simply on the attachment of an air bubble to either a small or low-density particle, or to a liquid droplet.

Method 1: Selective Separation

Mineral flotation has by far the greatest usage, processing 20 billion tons per year; however the process of delinking newsprint is currently at about 25 million tons per year and is expected to grow significantly in the next decade. In these operations the selective attachment of a bubble to the valuable or an unwanted component of a particle is required. In de-inking, this refers to the removal of ink particles from cellulosic fibres. For mineral processing, a higher degree of selectivity is required, to recover a valuable particle from a suspension of waste particles. This operation is very seldom used on its own but is part of a flowsheet in which, after pretreatment which includes size reduction, a solid suspension in water is fed to the flotation circuit.

In the circuit, cells may be arranged in sequence with each successive cell treating the concentrate

from the previous one to improve its purity; this is, called 'roughing'. The final concentrate from the rougher bank is fed to a bank of 'cleaning' cells. The reject stream from the last of the cleaning cells is itself recycled to improve the final recovery and is called 'scavenging'. The concentrate from the final scavenger stream is recirculated to the feed of the first of the rougher cells. The waste from the final scavenging cell is discharged as the overall plant waste. This may be recycled, or treated to minimize its environmental impact. The final cleaner concentrate is essentially the plant product, although it may also have to be processed possibly by recleaning and drying.

In waste paper, de-inking the ink-rich stream tailings appears in what in mineral processing is the concentrate and the de-inked paper in what is usually the mineral processing tailings.

Method 2: Non-Selective Separations

The other class of operations require only the non-selective attachment of air bubbles to a particle/droplet, producing an aggregate of high buoyancy, so that the attached material can be withdrawn from the top of the flotation vessel. Processes of this type include the off-shore recovery of crude oil which may be 5–50% oil by volume, containing dispersed oil in the form of 10–50 µm oil droplets in water. After processing, virtually all the oil is recovered containing only 0–5% water. Other processing operations of this class include water treatment, in which the rate of setting of the flocculants on their own is very slow while the buoyancy of the air bubble/flocculant is high. Also the separation of rejected plastics from general wastes is economically attractive, with polyethylene terephthalate (PET), polyethylene (PE),

polyvinyl chloride (PVC) and polypropylene (PP) being recoverable.

The effectiveness of any flotation separation is described by the fractional recovery of the desired material, R , in the concentrate stream and its purity, the Grade G . The practical application of this is a principle more honoured in the breach than the observance, and is an area where significant economic improvements are possible.

Method 3: Measures of Separation Efficiency Potentially Achievable

In mineral processing, it is convenient to represent both quantities on a plot $0 \leq R, G \leq 1$. The Grade G is defined as $1 - (1 - x_C)/(1 - x_F)$ where x_F and x_C are the mass fractions of the desired component in the feed and concentrate streams respectively, and the fractional recovery of the desired component $R = (Cx_C)/(Fx_F)$. A perfect separation is therefore one in which $R = G = 1$.

Actual simulations lie on the upper boundary of the Grade-Recovery plot and describe the best R at a defined Grade. The area on the plot whose upper boundary represents optimum operation is called the attainable region. The function of the research worker ultimately is to devise techniques whereby the attainable region may be expanded. The Grade-Recovery plot should also be used by operators to monitor and control plant performance. The applications of automatic feed back control is attractive, but the requirements of online instrumentation, such as image processing and chemical analysis detectors, are still in the development stage. This is particularly so with the control actions which are necessary to be able to compensate for deviations from optimum operations. These include changing in air flow rates and the addition of chemicals. It is in this latter area that there is a large measure of uncertainty, which should be addressed as it again offers the possibility of significant economic improvements. The treated tailings which are usually in great bulk still have to be disposed of, at a significant cost, sometimes requiring slime dams to be built or as landfill. This is an environmental factor which may be very costly, both in the operation of existing plants, and in assessing the viability of new projects. Recycling the waste is environmentally acceptable and may also be profitable.

Method 4: Macro Dry Separations

It is significant that siliceous materials can be floated as they may well be the source of gangue contamination in metallic ore flotation. These gangues are in general disadvantageous to the separation and may

have to be depressed. However the recycling of simple oxide materials such as corundum, haematite and goethite may well be valuable although floated at lower rates.

Ore-dressing – although this is not strictly a flotation operation – effectiveness determines the limiting separation achievable in the flotation circuit. In the first ore-dressing step, separation is based on size reduction and primary mechanical classification. Once again, the details of the circuit depend on the nature and throughput of the raw material to be processed. The general principles involve crushing followed by dry separation in spirals (which are in fact of a helical design). Crushing and dry separations such as screening are relatively cheap and their use should be maximized to achieve the cheapest possible separation of high value materials from those which are exclusively gangue. Of these dry separation methods, the spirals depend on the difference in density between the waste rock and the valuable material. Vibratory screens may follow or be operated in parallel with the spirals. These are only useful if the fines are largely gangue. The valuable-rich stream from the dry separations is then fed to rod and wet or dry ball mills, the product of which goes to hydrocyclones whose underflow is a solid suspension in water whose solids lie in the size range 50–500 μm . This is a size range at which the subsequent flotation operations will function satisfactorily. The fine product from the mills is aimed at producing two separate powder streams in which there is a sharp change in the valuable material content; this process is referred as the liberation of the valuable material. The power costs of milling are extremely high. The overflow from the cyclones are called slimes and go to settling tanks from which the final solids and liquid wastes may be recycled or discharged. These streams are the primary source of environmental pollution and are vulnerable to objections which may require new treatment techniques.

Method 5: The Characterization of the Solid Material

In flotation, the complete characterization of the solid material to be floated, which varies considerably for different materials, is fundamental to the separation. In paper de-inking the type of ink used and its method of attachment to the waste fibre, determines the nature of the process required. This again is an area in which the technology is still developing. In mineral separations for example, the chemical type of both the valuable material and the gangue have to be identified, and it is also crucial to be able to identify and determine the distribution of individual minerals,

throughout the solid matrix of the primary ore. A mineral may be present as individual grains whose boundaries are a source of mechanical weakness in the solid. This facilitates breakage at the grains following impact and also most interestingly, breakage at the grains following differential thermal effects generated in a microwave field. Alternatively, the mineral may be distributed uniformly throughout the solid matrix. The initial characterization is usually done by microscope examination which, in the hands of an experienced operator, is extremely informative, but which usually has to be supplemented by X-ray fluorescence (XRF) analysis.

Method 6: Wet Processing – Hydrodynamics of Cell Design

The practice of mineral beneficiation by flotation is based on the production of an aqueous suspension of particles in the micron-size range and a dispersion of bubbles in a millimetre-size range. It is the objective within this suspension to achieve particle–bubble collision which will be followed by a selective attachment of the particles. In terms of the method of interception/attachment there are two basic types of cell.

Mechanical Cells

In mechanical cells there is a relatively small inner turbulent region enclosed by a larger diameter quiescent zone. The turbulent region is generated by an impeller which in addition has to disperse air into the solid suspension, and then pump the aerated suspension into the quiescent zone. There are a plethora of designs available which have to be carefully evaluated. The design variations should be related to the achievement of a desired interception/attachment efficiency as a function of particle size. These cells are the most commonly encountered in industrial practice principally because they can have very high capacities, with single cells of up to 300 m³.

In the inner region the suspension is exposed to a high level of turbulence, in which particle–bubble interception depends on the different paths between the water eddies and the particle trajectories. Although there are no theoretical calculations to provide a basis for these effects, it is assumed that the interception efficiency is determined by the local turbulent intensity and is increased for large particle sizes with a large differential density between the particle and water. Unfortunately, there is a probability that large particles which have been attached to the bubbles, following the turbulent interception may subsequently become detached from the bubble surface. The detachment will be associated

with the overall strength of the attachment forces; as these forces are surface effects and the specific surface is low, their detachment probability is high. For the small particles with a high specific surface with an overall high attachment force, the detachment probability is low. It is however, also apparent that these smaller lighter particles, as they follow the eddies closely, will have lower interception efficiencies. The net degree of attachment of particles to bubbles will depend on the design of the agitators (impellers).

Cylindrical Vertical Column Cells

The second cell type takes the form of a cylindrical vertical column in which the suspension is dilute, typically containing 5% solids. In these cells the attachment of a desired particle is more specific than in the mechanical cells. These cells may be between 3 m in diameter and 15 m high. The cells are described by the collection and froth zones. There is also an intermediate zone between the top of the collection zone and the froth. This zone functions very similarly to the top of the collection zone. The solid suspension from the milling circuit is added to the top of the collection zone and the air as bubbles through a sparger at the bottom. The bubbles and particles move countercurrently through the relatively quiescent collection zone. The hydrodynamics of the collection zone are relatively easy to describe. Originally the probability P_c of interception was given by $P_c = 3/2 (r_p/r_b)^2$ where r_p and r_b are the spherical radii of the particle and bubble, respectively. The original equations have been approximately corrected to allow for gravitational effects in terms of a parameter $K = 2 (\rho_p r_p^2 U) / (9 \mu_f r_b)$ where U is the bubble rise velocity in water of viscosity μ_f and ρ_p is the particle density. P_c indicates some interesting dependencies on K , e.g. (i) there is a K_c which is approximately 1, below which no collision will occur; the smallest size galena particle that can collide with a 1.5-mm bubble is 30 μm ; (ii) from the definition of K , when it is $> K_c$, an increase in bubble size will increase the collision efficiency and; (iii) very fine particles follow the streamlines exactly and will only collide if the streamline brings them within 1 particle radius of the bubble. Maximum velocities of 0.9, 1.5, 2.2 and 2.7 mm bubbles have been observed to be respectively 25.0, 36.5, 3.47 and 32.0 cm s⁻¹. However caution has to be used using predictions based on K as anomalies have been observed, and more accurate equations are now available. Surface-active chemical frothers, e.g. Dowfroth 250 and methyl isobutyl ketone (MIBK), are normally added at concentrations of the order of 30 ppm, these are to stabilize the final froth. The effect of the presence of these frothers

is to reduce the bubble rise velocity by about 50%. The effect of the surfactants is to adsorb on the bubble surface, increasing the surface viscosity of the water near the bubble, and the bubble rigidity.

Method 7: The Recovery of a Specific Particle Size

The effect of particle size is dependent on interactions with various factors. The ultimate objective is to remove particles of size d_{lib} which is the size at which maximum liberation occurs. Even if the dry separation gives material with a perfect size distribution as the mill feed, there will be a distribution of sizes in the product from the mills, which is the feed to the flotation circuit. If this particle size distribution is $f(d_p)$, the fractional mass of the size d_p , as characterized by their valuable content, then the flotation circuit should aim to maximize the recovery of particles of this size and sizes close to it. Clearly $f(d_{lib})$ should have a maximum and a small standard deviation. Ideally this could take the form of a delta function giving $f(d_{lib}) = \delta(d_{lib}) = 1.0$. The following step is to ensure what spread in the size distribution in the removal of these valuable particles occurs in the flotation circuit. This will depend on the specificity of the interception/attachment efficiency achievable for these particles, with an $f(d)$ size distribution, in a flotation circuit.

The calculation for a specific circuit will depend on the performance of its cells. Consider the specificity of removal of particles in a single mechanical cell. In addition to the interception/attachment in the turbulent zone which has a spread of efficiencies, there is also attachment of particles in the quiescent (pulp) zone which may have a different distribution. There is also a restriction on the new upflow rate through the pulp; if it is too high, non-attached particles may be entrained, and if too low the bubble-particle aggregates may settle. The design problem for the cells is firstly to design an impeller which will produce to the optimum size range of valuable particles, while pumping water at a sufficient rate into the pulp for the necessary upflow in the quiescent zone, which as an optimum bubble size distribution, to maximize the recovery of $f(d_{lib})$.

The bubble-particle contact in mechanical cells is sensitive to variations in the size of both, and the cell has to be designed for optimal removal of particle sizes with a high degree of liberation. It is clear that the requirement of the maximum removal of valuable material is not easily met. The mill product will have a distribution of particle sizes, each size with a varying valuable content. The flotation circuit separation

should also separate the most valuable particles of a size close to d_{lib} . The design challenge is to design milling and flotation circuits capable of producing and removing a specific size. It is also the responsibility of the operators to ensure that the system is operated continuously at its optimum level. These are realistic objectives.

The separations achievable in columns is potentially far more selective than that of the mechanical cells but are restricted by a narrow operating range. The most effective particle size in a column is of the order of 75 μm with bubble sizes varying from about 0.8 to 2.5 mm. This size range may not be consistent with the peak liberation size. The height of the columns is determined by the need for bubbles to accelerate from the bottom to their terminal velocity, where interception is a maximum. At these conditions the loaded bubbles will entrain into the froth significant amounts of solution containing gangue. The most effective feature of the columns is the removal of these waste solids by adding wash water to the top of the deep froth column. The froth at its top surface will overflow with a maximum grade. In industrial practice, columns are used to upgrade (clean) the froth concentrate from the primary cells (roughers).

Method 8: Pulp Microprocesses

Attachment following the interception of a particle by a bubble depends on the magnitude of the surface forces between them. The characterization of these forces to generate selective attachment is possibly the key factor in the separation.

The particles are always dispersed in water and the nature of the wetting of their surfaces determines the effectiveness of air bubble attachment. For hydrophobic surfaces, the water film is weakly bound and would fail easily after impact, thus causing attachment. The selectivity of the separation can be enhanced by the adsorption of a surface-active agent, a conditioner. These have a polar end which attaches to the solid surface, and a non-polar end which sticks into the water making the surface hydrophobic. In a bubble-particle interception, the particle has a time of contact, the sliding time after the initial interception during which the particle and the bubble will be separated by a thin water film. The sliding time will depend on the initial displacement of the particle from the line of centres of the rising bubble and the settling particle. The rate of thinning will depend on the kinetic energy dissipation after impact and London-van der Waals dispersive forces, electrostatic interactions and capillary forces following distortion of the bubble surface during impact. If the film thins

to a critical thickness, it will fail, which results in a successful attachment. Both the thinning process and the critical thickness depend on the interaction energy at the particle–water interface.

The requirement of hydrophobicity as a basis for attachment is justified by the following theoretical treatment. The dispersion energy $\varepsilon(h_x) = -(1/12\pi)A/h_x^2$. The attraction stress between the two surfaces is then $(\partial\varepsilon(h_x)/\partial h_x) = A/(6\pi h_x^3)$ dynes cm^{-2} . A is the Hamaker constant which is of the order of 10^{-12} ergs. For a condensed system to describe the interaction stress, A is replaced by A_{132} which is a linear combination of two surface interactions only. A_{12} represent the interfacial energy between a particle 1 and a bubble 2 separated by a vacuum, A_{13} and A_{23} are the Hamaker constants representing the particle–water and bubble–water interaction energies respectively. A_{33} is the interaction energy between water molecules. The linear combination $A_{132} = A_{12} - (A_{13} + A_{23} - A_{33})$. If A_{13} and A_{23} representing the particle–water and the bubble–water interactions are low, then A_{132} will be greater than A_{12} . The enhanced attraction between particle and air bubble in the presence of water represents hydrophobic bonding.

Experimental characterization of hydrophobicity can be done using the contact angle. If a liquid droplet is placed on a solid surface at the three-phase point of contact, it will form a definite angle θ between the liquid and solid surfaces, which is called the contact angle. If ΔG^0 is the change in free energy of the three-phase contact, following a small change ΔA_s in the area of contact, then $\Delta G^0 = \Delta A_s(\gamma_{SL} - \gamma_{SV}^0) + \gamma_{LV} \cos(\theta - \Delta\theta)$ at equilibrium; this leads to the Young equation, $\gamma_{SL} - \gamma_{SV}^0 + \gamma_{LV} \cos \theta = 0$. Since γ_{SV}^0 is the energy of contact of a solid with a saturated vapour of partial pressure p^0 there is also present on the surface a film of condensed vapour with its own surface energy π^0 . Then the total surface energy of the solid surface is $\gamma_s = \gamma_{SV}^0 + \pi^0$. Substituting in the Young equation for γ_{SL} gives $\gamma_{LV} \cos \theta = \gamma_s - \gamma_{SL} - \pi^0$ in the Dupre equation, the work of adhesion $w_{SLV} = \gamma_{LV}(1 + \cos \theta) + \pi^0$. This relates an increase in θ to a reduction in adhesion energy or alternatively an increase in the surface hydrophobicity.

Electrical Effects

The charge on a solid surface can vary from mineral to mineral and forms a basis for selective separation. The charge is strongly bound close to the surface in the Stern layer while further from the surface the layer is diffuse. If the particle moves in an applied electrical field, a lower potential will be observed which is that at the border of the Stern and the diffuse layers. This is an electrodynamic effect

called the ζ potential. The ζ potential is a strong function of pH; the point where the ζ potential is zero is called the PZC (point of zero charge). For goethite (FeOOH) the PZC is 6.7 and at acid pH the zeta potential is positive. Using RSO_3 which has a negative polar group, the recovery of goethite is 100% below pH 4.5 and 0% above pH 6.7, while if dodecylammonium chloride which has a positive polar group is used, the recovery of goethite in acid solution is 0% while above pH 9.5 the recovery is 100%.

The attachment of bubbles to charged electrical surfaces is underresearched. The bubbles are stabilized by surfactants (frothers) whose polar end may be anionic, cationic or non-ionic. The hydrophobic end of their molecule will be inside the bubble while the polar end is in the water. After impact, the previous treatment suggests that if the electrical forces between the bubble and the particle surface are attractive then A_{132} will increase and conversely, if the two surfaces repel each other, A_{132} will decrease. This is mere speculation as experimental confirmation is held up by the extremely small frother concentrations on the bubble surface, and the difficulty in the determination of the bubble's charge.

Method 9: Froth Microprocesses

As the particle–bubble aggregates rise to the top of the pulp they entrain with them in their boundary layers a small but significant amount of the pulp suspension which contains both unattached valuable and waste particles. The bubbles loaded with valuable solids pass through the upper level of the pulp and form a froth. As they pass into the froth, they entrain with them pulp water. In the froth the void volume of the pulp suspension is reduced from that in the pulp, owing to closer packing of the loaded bubbles. This forms the interface between the pulp and the froth which is readily observable (Figure 1). The sharp reduction of water in the froth at the point is a preliminary drainage effect. Bubbles will rise through the froth until they either burst at the top surface or, as unbroken bubbles loaded with valuable particles, overflow the concentrate weir. This is the final product of a single cell; the unfloated waste product will settle to the bottom of the quiescent region and leave the cell in the tailings stream.

The performance of the froth depends on the stability of the bubble passing through it. This in turn depends on the amount of frother added. At high levels of frother, the individual bubbles will remain as small spheres and will leave over the concentrate weir essentially unchanged from their condition at the bottom of the froth. Their water content will therefore be unchanged and there will be no upgrading of

Figure 1 Pulp-froth interface.

the solid product. They will not burst at the top surface of the froth and will flow easily over the weir. With a lower level of frother addition, the spherical bubbles will deform to non-coalescing dodecahedra. The flat faces of the bubbles will be separated by lamellae with a size in microns (**Figure 2**). Water squeezed down the lamellae, flows into plateau borders which are of millimetre size; the three plateau borders at their ends join to form nodes down a network of which the entrained froth water drains back to the pulp. It has been reported that for two-phase foams, that the volumetric water content of the foam will fall from 0.26, at 5 mm from the pulp-foam

interface to 0.016, at 12 cm from the bottom of the foam. After that the value of 0.016 will remain constant through the foam. For coalescing foams the bubbles moving towards the weir will continue to grow, giving a lower volumetric water contents of < 0.01 . The effect of coalescence in a three-phase froth, will therefore be to increase the Grade, G , but with a decrease in fractional recovery, R , because of bubble breakage at the top surface of the froth.

Finally it may be observed that cells may potentially be controlled automatically with online image processing cameras.

Figure 2 Control of flotation cells by image processing the upper surface of their froths. (A) The bubble structure in inverted light and the same structure with bubble boundaries sharply demarcated. (B) and (C) A comparison between the image-processed bubble structures, in inverted and reflected light, respectively. (D) The bubble structure in reflected light with image-processed boundaries superimposed.

Introduction

Separations are possible in gas chromatography if the solutes differ in their vapour pressure and/or intensity of solute-stationary-phase interactions. As a minimum requirement the sample, or some convenient derivative of it, must be thermally stable at the temperature required for vaporization. The fundamental limit for sample suitability is established by the thermal stability of the sample and system suitability by the thermal stability of column materials. In contemporary practice an upper temperature limit of about 425°C and a sample molecular weight less than 1250 is indicated with only minor exceptions. A large number of general and selective derivatizing reagents are available for sample modification to enhance compound thermal stability, improve sample separation properties, and to provide compound-selective detection.

Column Types

Wall-coated open tubular columns (WCOT columns), or simply capillary columns, and classical packed columns dominate the practice of gas-liquid chromatography. Porous layer open tubular columns (PLOT columns) and classical packed columns dominate the practice of gas-solid chromatography. Classical packed columns are usually 0.5–3 m long with an internal diameter greater than 2 mm packed with adsorbent or liquid-coated support particles of 100–250 µm diameter. WCOT columns are typically up to 100 m long with internal diameters of capillary dimensions coated with a thin, and usually immobilized, film of stationary phase leaving an open interior passageway down the centre of the column. PLOT columns are identical to WCOT columns with the liquid phase replaced by a layer of fine adsorbent particles. WCOT and PLOT columns are the first choice for analytical separations because of their superior peak capacity and greater chemical inertness. Packed columns offer a lower cost choice for some applications, are easier to use, are relatively tolerant of thermally unstable and involatile sample components and are better suited to isolating prep-

arative-scale quantities of materials. Only a limited number of poly(siloxane) and poly(ethylene glycol) stationary phases have been successfully immobilized in WCOT columns compared to the larger number and variety of stationary phases available for use in packed columns.

Column Properties

The high permeability of WCOT columns allows long columns to be used to provide very high total plate numbers, as indicated in Table 1. Narrow-bore and thin-film columns are intrinsically the most efficient and are selected for fast chromatography. Since resolution increases only as the square root of the plate number, and also the column length, large values for the plate number are required for difficult separations. Such large numbers are available in gas chromatography, albeit at the expense of separation time, allowing separations to be achieved with only minimal differences in selectivity. In contrast to other chromatographic methods, separations in gas chromatography are often achieved through kinetic optimization, allowing many separations to be obtained on a limited number of stationary phases. A favourable feature of kinetic optimization is that the outcome is readily predictable from simple arithmetic calculations once some information of peak order has been established in a trial separation.

At a given temperature the partition coefficient is constant and the observed retention factor will depend on the phase ratio. The phase ratio is given by the column volume accessible to the mobile phase divided by the volume of stationary phase. Columns with a large phase ratio provide small retention factors for volatile compounds and require inconveniently large plate numbers to provide adequate resolution. Columns with a low phase ratio, that is, thick film columns, have a lower intrinsic efficiency than thin film columns, but provide better resolution of volatile compounds, because they provide more favourable retention factors. They also allow separations of volatile compounds at a higher and more convenient temperature range than is possible with thin film columns. For volatile compounds this often means at temperatures above room temperature as opposed to cryogenic temperatures. For high boiling compounds, columns with a low phase ratio are not

Table 1 Characteristic properties of some representative columns

Column type	Length (m)	Internal diameter (mm)	Film thickness (μm)	Phase ratio	Column plate number	Plates per metre
Classical packed	2	2.16	10%(w/w)	12	3 640	1 820
	2	2.16	5%(w/w)	26	4 000	2 000
WCOT	30	0.10	0.10	249	480 000	16 000
	30	0.10	0.25	99	368 550	12 285

	30	0.32	1.00	79	102 080	3 400
	100	0.32	1.00	79	304 200	3 400
	30	0.32	5.00	15	68 970	2 300
	10	0.53	1.00	132	23 500	2 340
	30	0.53	1.00	132	70 420	2 340
	10	0.53	5.00	26	14 700	1 470
	30	0.53	5.00	26	43 940	1 470
	50	0.53	5.00	26	73 200	1 470

useful because they lead to long separation times. Increasing the phase ratio by reducing the film thickness lowers the retention factors to a value within the optimum range so that there is little deterioration in resolution and faster separations are obtained. Packed columns have low phase ratios compared to most WCOT columns. For compounds of moderate and low volatility, separation times on packed columns are generally longer. Since several combinations of film thickness and column radius can be used to generate the same phase ratio, there are other factors that need to be considered for selecting these variables for a particular separation.

Mobile-Phase Selection

Nearly all separations are achieved with hydrogen, helium or nitrogen as the carrier gas. At temperatures and pressures typical of normal operation in gas chromatography these gases behave almost ideally, providing a transport mechanism for the sample without influencing selectivity. The exception is gas-solid chromatography where the carrier gas participates in the retention process through competition with the sample for stationary-phase adsorption sites. Differences between hydrogen, helium and nitrogen are not usually large but absolute retention and retention order can change as a function of the carrier gas type and average carrier gas pressure. Heavier carrier gases, such as carbon dioxide, are more effective at influencing retention in gas-solid chromatography than the common carrier gases.

Although the choice of carrier gas does not significantly influence selectivity in gas-liquid chromatography,

it can still influence resolution through its effect on efficiency. This results from differences in gas diffusivity. The separation time is also affected because the optimum carrier gas velocity decreases with solute diffusion rates. In pressure-limiting conditions, gas viscosity differences are important as well. Nitrogen provides lower plate heights but at a lower optimum velocity (Figure 1), leading to long separation times. Close to the optimum plate height region, the ascending portions of the curves are shallower for hydrogen and helium. Thus, for separations at mobile-phase velocities higher than the optimum velocity, hydrogen and, to a lesser extent, helium provide faster separations than nitrogen with little loss in efficiency. For thick-film columns ($> 0.5 \mu\text{m}$), diffusion in the stationary phase is a significant factor in zone broadening and the relative contribution of the carrier gas to separation performance and time are not as great. Thick-film columns should be operated close to the optimum velocity, with the choice of carrier gas being less significant. Nitrogen is often the preferred carrier gas for these columns. For packed columns nitrogen provides (slightly) higher efficiency at low temperatures and flow rates, while hydrogen is superior at higher temperatures and at above optimum velocities. Hydrogen is preferred in pressure-limited conditions because of its lower viscosity. A considerable difference in the relative cost of helium in the USA and Europe has resulted in different preferences on the two continents. For WCOT columns, helium is widely used in the USA for safety rather than theoretical considerations, while hydrogen is commonly used in Europe.

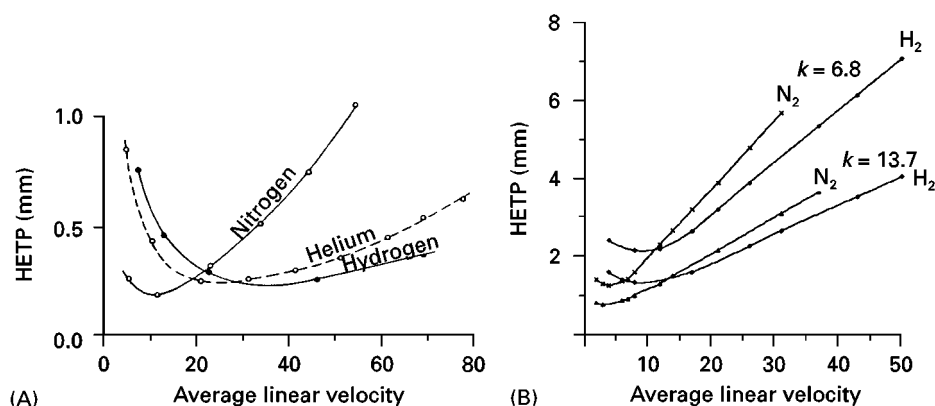

Figure 1 Influence of the choice of carrier gas on the efficiency of (A) a thin-film and (B) a thick-film WCOT column (k is the retention factor).

Stationary-Phase Selection

Given the nonsolvating properties of the mobile phase in gas chromatography, selectivity optimization is a matter of stationary-phase selection. Over the years thousands of substances have been evaluated as stationary phases and most abandoned in favour of a smaller number of liquids and adsorbents with favourable temperature operating ranges, kinetic properties and possibility of immobilization if used in WCOT columns.

Packed-column liquid phases can be roughly categorized into four groups:

1. hydrocarbon and perfluorocarbon liquid phases
2. ether and ester liquid phases

3. liquid organic salts
4. poly(siloxane) liquid phases

Representative examples and their useful temperature operating range are summarized in **Tables 2** and **3**. Most can be considered useful for general applications, except for the perfluorocarbon liquid phases that are used for the speciation of perfluorocarbon compounds or the separation of reactive compounds (metal fluorides, interhalogen compounds and non-metal halides) that tend to destroy conventional phases. The family of poly(siloxanes) provides the widest range of favourable stationary-phase properties and variation in selectivity. They are the most widely used stationary phases for packed-column

Table 2 Characteristic properties of some liquid phases used in packed-column gas chromatography

Name	Structure	Temperature range (°C)

gas-liquid chromatography and, because of their ease of immobilization, are the dominant stationary phases used to prepare WCOT columns (Table 4). With today's technology the only other family of stationary phases that can be immobilized for WCOT columns are the poly(ethylene glycols).

The selectivity of the stationary phases is of more interest than their chemical structure for method development. Liquid stationary phases have been classified based on their solvent strength (polarity) and selectivity. Classification based on the idea of polarity has had to be abandoned because of the lack of a working definition. Selectivity is defined as the relative capacity of a stationary phase for specific intermolecular interactions, such as dispersion, induction,

orientation and complexation (including hydrogen bond formation). Unlike solvent strength (polarity) it should be feasible to devise experimental scales of stationary-phase selectivity. Modern approaches to stationary-phase classification by selectivity are based on the cavity model of solvation. This model assumes that the transfer of a solute from the gas phase to solution in the stationary phase involves three steps. Initially a cavity is formed in the stationary phase of the same size as the solute. The solute is then transferred to the cavity with reorganization of solvent molecules around the cavity and the set-up of solute-solvent interactions. Retention in gas-liquid chromatography, therefore, will depend on the cohesive energy of the stationary phase, represented by the

free energy required for cavity formation, the formation of additional dispersion interactions of a solute-solvent type, and on selective solute-solvent polar interactions dependent on the complementary character of the polar properties of the solute and stationary phase. Quantitatively, these interactions are described by the solvation parameter model set out below in the form suitable for stationary-phase classification:

$$\log k = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + l \log L^{16} \quad [1]$$

where k is the retention factor. The remainder of the equations is made up of product terms called system constants (r, s, a, b, l) and solute descriptors ($R_2, \pi_2^H, \Sigma\alpha_2^H, \Sigma\beta_2^H, \log L^{16}$). Each product term represents a contribution from a defined intermolecular interaction to the solute property. The solute descriptors are free energy-related solute properties known for about 4000 compounds with others available by estimation or from experiment. They are not of immediate interest to us here except to note that once the system constants are established, the retention property of any solute with known or easily estimated solute descriptors can be estimated for that system by simple arithmetic calculation using the model described. The system constants (also called phase constants in gas chromatography) contain the information of the stationary-phase properties and provide an unambiguous means of classification. The r phase constant refers to the ability of the stationary phase to interact with solute n - or π -electron pairs. The s phase constant to the ability of the stationary phase to take part in dipole-type interactions. The a phase constant is a measure of stationary-phase hydrogen bond basicity and the b phase constant a measure of stationary-phase hydrogen bond acidity. The l phase constant describes (in part) the contribution of cavity formation and dispersion interactions to retention and, more specifically, indicates the ability of the stationary phase to separate members of a homologous series. The phase constants for any stationary phase can be determined through the method of multiple linear regression analysis by measurement of a retention property for a series of varied solutes with known solute descriptors.

The stationary phase constants for a number of common liquid phases at a reference temperature of 121°C are summarized in Table 5. The system constants in Table 5 are only loosely scaled to each other so that changes in magnitude in any column can be read directly, but changes in magnitude along rows must be interpreted more cautiously. Most stationary

phases possess some capacity for lone-pair electron interactions (r constant), but selectivity for this interaction is all but nonexistent among common stationary phases. Fluorine-containing stationary phases have negative values of the r constant representing the tighter binding of electron pairs in fluorocarbon compared to hydrocarbon groups. Lone pair electron interactions do not usually make a significant contribution to retention in gas-liquid chromatography and are not considered a primary means of selectivity optimization. The most striking feature of Table 5 is the paucity of stationary phases with significant hydrogen bond acidity (b constant). In the case of EGAD, DEGS and TCEP, the small b phase constants indicated in Table 5 are probably a product of impurities and thermal modification of the stationary phases during use rather than a fundamental property of the stationary phases themselves.

A few novel stationary phases with strong hydrogen bond acid properties have been synthesized recently, but none of these are commercially available. Stationary-phase hydrogen bond acid interactions, therefore, do not contribute significantly to method development strategies for the commonly used stationary phases. The only practical exception seems to be the poly(trifluoropropylmethylsiloxane) WCOT column stationary-phase DB-210, which exhibits some weak hydrogen bond acidity, presumably acquired through the immobilization process that is absent from the structurally similar packed-column stationary phase QF-1. That leaves the most important stationary-phase properties for selectivity optimization as their cohesive energy and capacity for dipole-type and hydrogen bond base interactions.

Cluster analysis provides a visual picture of the difference in selectivity for different stationary phases and a classification of their properties into groups of similar selectivity (Figure 2). The stationary phases most similar to each other are next to each other and are connected. Connections at the extreme left-hand side of the dendrogram occur for phases with similar properties and those towards the right-hand side with greater degrees of difference. Stationary phases with no paired descendents are singular phases with properties that cannot be duplicated by the other phases. The stationary phases are classified into five groups with three phases behaving independently. Group 1 contains squalane, Apolane-87, OV-3, OV-7, SE-30 and OV-105. These are phases of low cohesive energy with minimal capacity for polar interactions. The second group of stationary phases contains OV-22, OV-25, OV-11, OV-17, PPE-5 and DDP. These phases have low cohesive energy and are weakly dipolar and hydrogen bond basic. QF-1 is loosely connected to this group but is significantly

more dipolar and has a more significant and opposite capacity for lone pair electron interactions. The third group contains OV-330 and OV-225 with UH50B loosely connected to this group. Compared to the second group these stationary phases are more dipolar and hydrogen bond basic and slightly more cohesive. They represent an increase in the intensity of the same range of interactions as the group 2 stationary phases. The fourth group contains the liquid organic salts with QBATAPSO distinguished within this group by its greater cohesive energy. Phases in this group are dipolar and the strongest hydrogen bond bases. The fifth group of solvents is divided into two subgroups. TCEP and OV-275 are strongly dipolar, hydrogen bond basic and have high cohesive energy.

EGAD, CW20M and DEGS have a similar range of polar interactions, but not quite as intense, and have a lower cohesive energy. For selectivity optimization in packed-column gas chromatography, a single phase is initially selected from each group. Subsequently, for fine-tuning additional phases are selected from within the group, identified as possessing the desired separation properties.

For historical reasons stationary phases are classified at a common reference temperature of about 120°C. The capacity of a stationary phase for specific intermolecular interactions determined at one temperature can be misleading for selectivity optimization at other distant temperatures. The broad outlines in Table 5 and Figure 2 remain true but changes in

Figure 2 Nearest neighbour complete link cluster dendrogram for some common stationary phases. The abbreviations for the stationary phases are identified in Tables 2, 3 and 5.

rank order due to cross-overs occur at different temperatures. Also, selectivity differences between individual stationary phases are enhanced at low temperatures with phases becoming more alike at higher temperatures. Information on the contribution of polar interactions to retention at high temperatures is scarce. These contributions could be small and stationary-phase selectivity differences rather limited at high temperatures.

Gas-solid chromatography is used for a narrower range of separations than gas-liquid chromatography. Because of higher retention, typical applications are the separation of fixed gases, volatile hydrocarbons, halocarbons, organic solvents and sulfur gases. The presence of immobilized active centres enhances the separation of isomers and isotopes. These separations are often difficult or impossible with liquid phases. A rough guide to the selection of sorbents for particular applications is given in Table 6. PLOT columns provide higher efficiency, faster separations and faster column regeneration compared to packed columns. Surface coating with inorganic salts and small amounts of liquid phase are used to extend the molecular weight separation range with inorganic oxide and carbon sorbents and to optimize selectivity.

PLOT columns generally require greater care in their use than WCOT columns. Other features include lower efficiency than WCOT columns, limited sample capacity and high activity.

General Elution Problem

In gas chromatography there is an approximate exponential relationship between retention time and solute boiling point at a constant (isothermal) column temperature. Consequently, it is impossible to establish a suitable compromise temperature for the separation of mixtures with a boiling point range exceeding about 100°C. This is generically referred to as 'the general elution problem' and is characterized by long separation times, poor separations of early eluting peaks and poor detectability of late eluting peaks due to zone broadening. The general solution to this problem is the use of programmed temperature and flow separation modes. Neither constant nor programmed modes are superior to each other. They are complementary, with the properties of the sample deciding which approach is adopted.

Temperature programming is the most popular programmed separation mode in gas chromatography.

Table 6 General applications of PLOT columns in gas chromatography

Stationary phase	Maximum operating temperature (°C)	Typical applications
Alumina oxide	200	Alkanes, alkenes, alkynes and aromatic hydrocarbons from C ₁ to C ₁₀ . C ₁ and C ₂ halocarbons
Silica gel	250	Hydrocarbons (C ₁ to C ₄), inorganic gases, volatile ethers, esters and ketones
Carbon	350	Inorganic gases and hydrocarbons (C ₁ to C ₅)
Carbosieves	150	C ₁ to C ₆ compounds
Molecular sieves (5A and 13X)	350	Hydrogen, oxygen, nitrogen, methane and noble gases Hydrocarbons (C ₁ to C ₃) on 5A with higher alkanes on 13X (up to C ₁₂) but not isomer separations
Porous polymers		
Q	310	Hydrocarbons (C ₁ to C ₁₄), halocarbons (C ₁ and C ₂), volatile oxygenated solvents
S	250	(C ₁ to C ₆), thiols, amines, nitro compounds, nitriles, water and inorganic gases
U	190	

Q, Poly(divinylbenzene-styrene); S, poly(divinylbenzene-vinylpyridine); U, poly(divinylbenzene-ethylene glycol dimethacrylate).

Stationary phases of high thermal stability allow wide temperature ranges to be used and temperature is easily adjusted and controlled. Temperature programme techniques are the most useful approach for scouting the properties of an unknown sample and are compatible with the large volume injection modes employing low temperature solute refocusing used in trace analysis. Flow programming is easily achieved with instruments fitted with electronic pressure control but is limited by the narrow pressure range which is usually available. It can be used to separate thermally labile compounds at a lower temperature than required for temperature-programmed separations. On the other hand, flow programming results in a loss of efficiency for late eluting peaks and presents difficulties in calibrating flow-sensitive detectors.

A temperature programme consists of a series of changes in the oven temperature and includes isothermal and controlled temperature rise segments. In essence, most programmes are simple, consisting of an initial isothermal period, a linear temperature rise segment, final isothermal period at the temperature reached at the end of the rise segment, and a cool-down period to return the oven to the starting temperature. The initial and final isothermal periods are optional, the temperature rise segment can be selected over a wide range (0.1 to *c.* 100°C min⁻¹), nonlinear changes in temperature may be used (extremely rare) and for complex mixtures, several linear programmes may be used in sequence to optimize the separation. The initial oven temperature is selected with due consideration to the resolution of the earliest eluting peaks in the chromatogram. If the temperature chosen is too high, the resolution of the initial peaks may be inadequate and, if it is too low, resolution may be acceptable but the separation time will be extended needlessly. The final temperature should be

selected so that the termination of the temperature rise segment and elution of the last sample component coincide unless the last few eluting peaks are particularly difficult to separate and require an isothermal period. Peaks eluting after completion of the temperature rise segment will be wider than those eluted during the programme. The selection of the heating rate represents a compromise between the necessity of maintaining a minimum acceptable resolution for the sample and the desire to reduce the separation time. This is governed largely by the complexity of the sample and its boiling point range. For samples containing components of different polarity temperature-induced changes in selectivity make the prediction of the resolution of closely spaced peaks a problem. Certain generalities can be made however. For the most difficult separations a slow heating rate will usually provide the optimum resolution. The separation time of weakly retained solutes is more readily adjusted by changing the flow rate of the carrier gas than the heating rate. For strongly retained solutes increasing the heating rate causes a proportional decrease in the separation time at a constant carrier gas flow rate. The retention time of well-retained solutes are less affected by changing flow rates in temperature-programmed gas chromatography.

The lack of an exact mathematical model to describe temperature-programmed separations makes computer simulation for their rapid optimization difficult. Simplex optimization of experimental variables and a model based on the linear elution strength approximation have been used with some success. The linear elution strength approach has the advantage that it only requires experimental data from two temperature-programmed separations of a sample using different programme rates. A series

of empirical equations are then employed to predict optimum separation conditions using relative resolution maps.

Generic Method Development

Method development commences with a definition of the problem and a review of available resources. Some pointers are given in Table 7. The separation of enantiomers requires special stationary phases and some separations of isomers use liquid crystal stationary phases that are not common laboratory items. Fast separations require special equipment and truly fast separations are only possible for simple mixtures. The separation of complex mixtures can be speed-optimized but not necessarily performed quickly on the same timescale used for simple mixtures. Preparative separations are usually performed with packed columns unless only a small amount of material

is to be isolated. Most analytical separations are performed using WCOT and PLOT columns, except for reasons noted earlier. A general guide to the selection of column types and dimensions is given in Table 8. For a sample of unknown composition a generic method for sample evaluation is provided in Table 9. These instruction sets will work for most simple mixtures and provide a starting point for difficult samples.

Injection and Detection Considerations

The choice of sample inlet depends on the injection volume, concentration of analytes, thermal stability of the analytes, concentration of involatile matrix components, volatility range of the analytes, relative volatility difference between the analytes and

Table 7 Defining the problem and utilizing available resources to formulate a solution

Problem definition

How many detectable compounds are present in the sample?

This is the only way to know that a separation is complete. It indicates the complexity of the problem, if only because, statistically, as the number of components requiring separation increases, so does the difficulty of achieving the separation. Fast separations are not easy for complex mixtures

Are all components equally relevant?

The only separation required is that of the compounds of interest from each other and all other compounds in the sample. The latter compounds can be considered as matrix components and need not be individually separated. This reduces the difficulty of providing a separation fit for the defined purpose

Are standards available for the compounds of interest?

This enables peaks to be tracked through initial trial separations and links difficult-to-separate compound pairs to their structure so that informed changes to the separation system can be made. It is required for calibration if quantification is needed

What is the concentration range of relevant compounds?

Trace components may initially be missed because of inadequate dynamic range if only the major components are considered. Particular injection techniques and selective detectors may be required to detect some compounds at anticipated concentrations

Is identification of unknowns required?

If unknown compounds are to be identified, retention information alone will be inadequate in most cases. Coupling to mass or infrared spectroscopic detectors is usually required to achieve the desired level of confidence in the result

Resources

Literature describing similar separations

Substantial databases of the chromatographic literature in an electronic searchable form are available. Column manufacturers' catalogues contain information on the separation of common sample types and certified columns may be available for mixtures subject to routine analysis. Official methods controlled by regulatory agencies usually specify appropriate columns for the separation

Past experience with similar samples

Life is a learning experience and there is no substitute for a good memory. What worked in a previous case for a similar sample is probably a good starting point for the new sample. Colleagues may have an informed opinion based on a different lifetime experience

Availability of certain columns and equipment

Resources are restricted to available columns and equipment and an evaluation of whether they will provide the information required is performed. Additional resources may have to be purchased or informed decisions made of the suitability of substituting available for desired resources

Compound information from handbooks

Structures, molecular weight, boiling point (or vapour pressure), solubility in common solvents is useful information that can be found in handbooks for many compounds which are identical or similar to the compounds of interest. This is useful for stationary-phase selection, derivatization strategies and detector selection

Table 8 Guide to the selection of WCOT columns*Column internal diameter*

- Use 0.25 mm i.d. columns for normal split and splitless injection unless sample overloading is a problem
- Use 0.32 mm i.d. columns for splitless and on-column injection, especially when injecting large sample amounts
- Use 0.53 mm i.d. columns as a replacement for packed columns, for the separation of samples containing < 30 components, or samples with components spanning a wide concentration range
- Use 0.18 mm i.d. (or less) columns when the maximum efficiency is required and for high speed separations (modifications to standard instruments may be needed)

Film thickness

- Standard film thicknesses are used for most applications (0.25 μm for 0.25 and 0.32 i.d. columns)
- Use thin film columns (0.1–0.25 μm) for solutes of low volatility (e.g. waxes, triglycerides, steroids, etc.)
- Use thick film columns (1–5 μm) for volatile solutes (e.g. solvents, gas-purgeable compounds)
- Choose columns with a similar phase ratio to obtain similar retention (larger phase ratios reduce retention)

Stationary phase

- If the sample composition is unknown, begin with a nonpolar stationary phase such as a poly(dimethylsiloxane) or poly(dimethyldiphenylsiloxane) with a low mol fraction of diphenylsiloxane groups that separate mainly by differences in volatility
- To improve selectivity, choose a stationary phase whose polarity best matches that of the solutes (similar dipolarity or complementary hydrogen bond interactions). See Figure 2 for the systematic identification of suitable stationary phases
- Consider using a PLOT column for the separation of light hydrocarbons and gases (other applications are indicated in Table 6)

Set-up conditions

Internal diameter (mm)	0.18	0.25	0.32	0.53
Flow rate (mL min ⁻¹)				
Hydrogen, $u = 40 \text{ cm s}^{-1}$	0.6	1.4	2.4	5.2
Helium, $u = 20 \text{ cm s}^{-1}$	0.3	0.7	1.2	2.6
Sample capacity (μg)	< 0.05	0.05–0.1	0.4–0.5	1.2
Separation number	40	30	25	15
Separation efficiency ($n \text{ m}^{-1}$)	5300	3300	2700	1600

solvent, and the required accuracy and precision. Split injection is commonly used for evaluating separation conditions, even if a different injection technique is used for routine applications. Split injection involves offline vaporization and mixing of the sample vapours with the gas phase, a portion of which is the carrier gas flow for the column and is

responsible for transporting a fraction of the sample into the column. Sample bands are narrow, preserving the resolving power of the column. Split injection can handle samples containing involatile matrix components and is the preferred method for injecting gases and volatile samples such as solvents. Accuracy and precision are often poor compared to

Table 9 Generic exploratory conditions for the separation of a sample of unknown composition

Stationary phase	Nonpolar poly(dimethylsiloxane) or poly(dimethyldiphenylsiloxane) with 5 mol% diphenylsiloxane groups
Column	Length 10–30 m Internal diameter 0.25 or 0.32 mm Film thickness 0.25 μm (1.0 μm for volatile compounds)
Flow rate	u_{opt}
Temperature	Programme from 50 to 300°C at 20°C min ⁻¹ (or to temperature limit for phase) Note the elution temperature (T_{E}) and range of T_{E} values T_{E} range < 25°C isothermal analysis T_{E} range > 25°C programmed analysis
Isothermal	Optimize range of retention factors (k). T_{opt} found from plot of $\log k$ versus $1/T$
Programmed	From original programme: 1 Select T initial ($T_{\text{E}} - 20$ for first component) 2 Select T final ($T_{\text{E}} + 20$ for last component) 3 Programme rate selected based on complexity. Simple mixture 10°C min ⁻¹ or higher and complex mixture 1–2°C min ⁻¹
Injector/detector	Initially high (c. 350°C). Reset, based on findings in trial chromatograms
Temperature	c. 25°C higher than the final column temperature
Injector	Split with a split ratio 1 : 50 to 1 : 100
Detector	Universal (flame ionization detector)

other injection techniques and sample information is not preserved for mixtures of a wide volatility range. Splitless injection allows larger sample volumes to be injected for trace analysis but requires an effective refocusing mechanism using cold trapping or solvent effects. Optimization of injection conditions is relatively complicated and time-consuming but accuracy and precision are good for favourable cases. On-column injection is the most accurate and precise injection technique but is limited to small sample volumes and requires relatively clean extracts. Programmed temperature vaporization injection is able to emulate all of the above injection methods as well as allowing large volume injections in the solvent-venting mode. Injection techniques using flash vaporization place the greatest thermal stress on the sample and are unsuitable for labile compounds. All methods can be automated, resulting in improved accuracy and precision compared to manual injection techniques.

Gas chromatography is blessed by a number of reliable and near universal and selective detectors (Table 10). Interfacing of gas chromatography to spectroscopic detectors for structural elucidation as well as quantification is straightforward and reduced to routine practice. For general applications the flame ionization detector is difficult to eclipse. It is sensitive, rugged, has a wide linear range, and it has a near universal response to carbon-containing compounds. It has a poor response to the noble gases and certain simple organic compounds containing a single carbon atom bonded to nitrogen, oxygen or sulfur. Thermal conductivity or helium ionization detection can be used for these compounds. A wide range of element-selective detectors and structure-selective de-

tectors has been developed for particular applications demanding matrix discrimination, low sample detectability, or for portable instruments. There are few situations encountered in gas chromatography where the identification of a suitable detector is the limit to progress.

Introduction: Steps in Method Development

Development of a method for a high performance liquid chromatography (HPLC) separation can be a major undertaking. Before the separation can be made, the sample must be in a suitable form to inject, and pretreatment steps are often required to remove major interferences or materials that might shorten the column life. After conditions for adequate separation are determined, some level of method validation is usually performed. Sample pretreatment and method validation are beyond the scope of the present discussion, which concentrates on achieving separation. This article describes only the major steps that are required for most samples. For additional information, the reader is urged to consult the reference by Snyder *et al.* (see Further Reading) which covers HPLC method development in detail. Additional method development information can be found in the other monographs listed.

General Approach

There are different approaches to HPLC method development, but we will follow the steps outlined in Table 1 and discussed below. For most samples, this approach provides the highest probability of success with the minimum investment in time and effort.

The first step in HPLC method development is to choose a chromatographic mode or method type. The most common modes are reversed-phase, normal-phase, ion exchange and size exclusion. User surveys over the last 10 years consistently show that most separations are performed using reversed-phase col-

umns. For the present discussion, reversed-phase separation is assumed. The following section gives a brief description of the use of alternative HPLC modes for special samples.

Once a mode is selected, the next step is to find conditions that will provide a separation of most of the sample components. When this has been achieved, it is then possible to estimate the effort that will be required to obtain an adequate separation of all components. This first step can be accomplished using either gradient or isocratic elution. We favour an initial gradient run, because all peaks are likely to elute in a defined time with reasonable separation of both early and late peaks. Usually several isocratic runs are required to achieve a similar result, and often no isocratic conditions will provide an acceptable separation. From the initial gradient run it is possible to estimate whether isocratic elution is possible. If this is the case, it is also possible to estimate conditions that give reasonable separation of most sample components.

As soon as this minimal separation is obtained, the chromatogram should be examined for problems related to peak shape. Most obvious are peak tailing problems. Although perfectly symmetrical peaks are preferred, many separations (usually for samples that contain basic compounds) will have one or more peaks that exhibit tailing. Most workers will accept peaks with asymmetry factors, $A_s \leq 2.0$ (United States Pharmacopeia (USP) tailing factor, $T_f \leq 1.7$). More severe tailing suggests the presence of unwanted sample interactions with the stationary phase. The most common fixes for tailing bands, in order of decreasing usefulness, are:

1. the use of columns designed for the separation of basic samples (based on very pure, type B silica);
2. adjustment of pH;
3. addition of triethylamine as a tailing suppressor;
4. use of ion pairing;
5. switching to a nonsilica (e.g. polymeric) column.

Symmetrical peaks that are too broad can also signal poor chromatographic behaviour; e.g. when column plate numbers, N , for the sample are $< 60\%$ of the column manufacturer's test report. Broad peaks can result from the use of too strong a sample solvent, injection volumes that are too large, column overload or column problems. Usually it is advisable

Table 1 General approach to HPLC method development

Select HPLC method
Obtain minimal separation
Check for and correct peak shape and width problems
Fine-tune primary variable
Change additional variables
Adjust column conditions

first to repeat the separation on a new column, to be sure that the problem is caused by a bad column. Reducing the injection volume to $< 25 \mu\text{L}$, keeping the injected mass $< 10 \mu\text{g}$, matching the injection solvent with the mobile phase and increasing the column temperature are some possible approaches to sharpening broad peaks.

Once acceptable peak shape is obtained, the next step is to fine-tune the primary variable: the percentage of organic solvent in the mobile phase, %B, for isocratic separations, or gradient time, t_G , for gradient elution. In general, weaker (lower %B) isocratic mobile phases or shallower (larger t_G) gradients will increase resolution at the expense of longer run times and broader peaks (with lower detection sensitivity). The best separation depends on the relative importance of peak resolution, run time and detection sensitivity, and will usually correspond to an intermediate value of %B or t_G .

An example of the effect of isocratic solvent strength (%B) on retention and selectivity is seen in **Figure 1** for the simulated separations of eight aromatic compounds. It is seen that retention and bandwidth increase inversely with %B. In general, R_s also increases, but not for every peak pair – only seven out of the eight peaks are visible at 70% and 50%B. Note the relative forward movement of benzene from 70%B, where it co-elutes with 2-nitrotoluene to 50%B, where it co-elutes with 2,6-dinitrotoluene; at intermediate solvent strengths it is resolved from neighbouring peaks.

Figure 2 shows the effect of gradient time (t_G) on retention and selectivity for simulated separations of a proprietary mixture of 11 herbicides. Retention and bandwidth increase with increasing t_G . The overall resolution increases with longer gradients, but note that peak 7, which elutes after peak 6 in the 20 min gradient, moves ahead of peak 7 with longer gradient times.

When satisfactory separation cannot be obtained by adjustment of the primary variable (%B or t_G), the usual problem is one of overlapping bands or selectivity. In the latter case, other conditions (mobile phase, column packing, temperature) can be varied. For example, we recommend starting with acetonitrile as the B solvent. Changes in selectivity are often observed if methanol or tetrahydrofuran is used instead of acetonitrile. Other variables worth examining are column temperature, pH (for ionic samples), use of ion-pairing reagents (ionic samples) and different types of stationary phase (e.g. change from C_{18} to a cyano or phenyl phase).

The final step in method development is to adjust so-called column conditions: flow rate, column dimensions and/or packing particle size. Typically,

sample resolution increases only slowly with decrease in flow rate or increase in column length, while run time increases much faster. If resolution is greater than required, this means that an increase in flow rate and/or decrease in column length can be used for a significant decrease in run time with acceptable loss in resolution. Smaller particle columns are typically used in shorter lengths; these small particle columns can provide shorter run times without loss in resolution or increase in column pressure. The column pressure drop (or system pressure) increases with higher flow rates, longer columns and smaller particles. Since it is desirable to maintain a system pressure $< 200 \text{ atm}$, this places a further constraint on the latter column conditions.

The simulated chromatograms of **Figure 3** show the effect of changes in column conditions on the aromatic sample of **Figure 1**. The lower run is the same as the middle run of **Figure 1**, using a 250 mm, $5 \mu\text{m}$ particle column with a flow rate of 2 mL min^{-1} , generating $R_s = 2.0$ in 11 min with 100 bar back pressure. By changing to a 150 mm, $3.5 \mu\text{m}$ column at the same flow rate, the run time is reduced to 6 min. For many applications, the narrower peaks (and thus lower detection limits) and shorter run time will be worth the minimal loss in resolution and increase in pressure ($R_s = 1.85$, 120 bar back pressure). If lower resolution is acceptable, a shorter column (75 mm, $3.5 \mu\text{m}$) at a higher flow rate (4 mL min^{-1}) will reduce the run time to $< 2 \text{ min}$, as shown in **Figure 3C** ($R_s = 1.15$, 120 bar back pressure).

Choice of HPLC Mode

Reversed-phase HPLC will prove adequate for most samples. Sample types requiring other chromatographic methods are summarized in **Table 2**. For samples that fall in one of these categories, consult the Further Reading section for detailed instructions.

Choice of Starting Conditions

A recommended set of starting conditions is summarized in **Table 3**. A C_8 or C_{18} column is chosen, with no particular preference for either phase. The $150 \times 4.6 \text{ mm}$ column size packed with $5 \mu\text{m}$ particles is capable of achieving most separations; with flow rates of $1\text{--}2 \text{ mL min}^{-1}$, run times are usually $< 15 \text{ min}$. One of the newer type B (low metal) silicas is strongly recommended for optimum peak shape and better column-to-column reproducibility.

Acetonitrile–water is recommended as mobile phase, because of its lower viscosity (and lower pressure drop), as well as its ability to be used with low

Figure 1 Simulated chromatograms for isocratic separations of aromatic compounds on a C_{18} column using water–acetonitrile mobile phases. (A) 70%; (B) 65%; (C) 60%; (D) 55%; (E) 50% acetonitrile. Samples: nitrobenzene, 2,6-dinitrotoluene, benzene, 2-nitrotoluene, 4-nitrotoluene, 3-nitrotoluene, 2-nitro-1,3-xylene, and 4-nitro-1,2-xylene (in retention order).

wavelength UV detection (≥ 190 nm; required for assay of some samples). If ionizable compounds are present in the sample, a buffer should be used. Phosphate at pH 2.5 is recommended for the initial separation, but note its reduced solubility for $> 80\%$ acetonitrile–buffer. When a volatile buffer is needed for liquid chromatography–mass spectrometry (LC-

MS) applications, 0.1% trifluoroacetic acid (pH 1.9), formic acid or ammonium acetate can be used.

The column should be thermostatted to maintain constant temperature and retention times; 5–15°C above room temperature is recommended for the initial separation. Temperature can be further adjusted to change selectivity if necessary. A sufficient

Figure 2 Simulated chromatograms for gradient separations of a proprietary herbicide mixture with a buffer–acetonitrile mobile phase. 5–80% acetonitrile in (A) 20; (B) 30; (C) 40 min.

weight of sample must be injected to obtain adequate detection sensitivity, but weights $> 10 \mu\text{g}$ should be avoided initially. Similarly, sample volume should be $< 50 \mu\text{L}$ to avoid excess band broadening.

Control of the Separation: Selection of Conditions

The selection of conditions for an HPLC method is expedited by a systematic approach. Because the goal of most separation development is to establish resolution for some or all peaks in a chromatographic run, we will use the fundamental resolution equation (eqn [1]) as a guideline:

$$R_s = \frac{1}{4}(N^{0.5})(\alpha - 1)(k/(1 + k)) \quad [1]$$

i ii iii

Figure 3 Simulated chromatograms for the sample shown in Figure 1 (60% acetonitrile) when column conditions are varied. (A) 250 mm, $5 \mu\text{m}$ particle column at a flow rate of 2 mL min^{-1} ; (B) 150 mm, $3.5 \mu\text{m}$ at 2 mL min^{-1} ; (C) 75 mm, $3.5 \mu\text{m}$ at 4 mL min^{-1} (expanded scale in upper right).

Table 2 Preferred HPLC methods and columns for different samples

Sample characteristics	Preferred HPLC method/column
High molecular weight	Special columns usually required Size exclusion and ion exchange HPLC often preferred
Optical isomers (enantiomers) present	Special chiral columns required
Other isomers (stereo-, position, etc.)	Normal-phase often best, especially with unmodified silica
Mixtures of inorganic salts	Ion chromatography
Carbohydrates	Amino-bonded phase columns with reversed-phase conditions; ion exchange resins
Biological samples	Special conditions often required for life science samples; may not require different approach
Hydrocarbon mixtures	Normal-phase with unmodified silica

where R_s is the resolution, N is the column plate number, α is the separation factor (selectivity), and k is the retention factor. The influence of each of these variables on the separation is discussed below.

Control of Retention

Term iii of eqn [1] varies with solvent strength. For reversed-phase separations, increased % B increases solvent strength, reduces sample retention (values of k), and reduces the size of term iii (and the value of R_s). The retention factor, k , is calculated using eqn [2]:

$$k = (t_R - t_0)/t_0 \quad [2]$$

where t_R is the retention time and t_0 is the column dead time. In general, as k increases, resolution and run time increase while bandwidth increases and peak height (sensitivity) decreases. For the best chromato-

graphic performance, separations in which $0.5 < k < 20$, or better $1 < k < 10$, are preferred. If k is too small (low retention), resolution is often poor because peaks tend to bunch at t_0 , while interferences from unretained sample components can also be a problem. When k is too large, run times are excessive, and detection sensitivity suffers because of wide peaks. Because of the major effect of solvent strength on separation, the selection of an acceptable value of % B should be the first priority. As will be seen in the following section, separation selectivity may also be affected by % B . Examples of the effect of % B on the separation were discussed earlier in conjunction with the chromatograms of Figure 1.

For isocratic method development, the rule of three can be used as a guideline to adjust retention by varying % B . The rule of three states that retention (or k) changes about threefold for a 10% change in mobile-phase % B . Thus, a change from 50% methanol to 60% methanol will reduce retention times by about three times. Similarly, a 20% B change will cause a 3×3 or about 10-fold change in retention. A convenient way to select a value of % B for isocratic separations is to start at 90% or 100% B and reduce % B in 10% steps until retention is in a reasonable range, then carry out final small adjustments in this variable.

Control of Selectivity

The selectivity term, ii, of eqn [1] is based on the separation factor α , defined in eqn [3]:

$$\alpha = k_2/k_1 \quad [3]$$

where k_1 and k_2 are values of k for the first and second peaks of interest, respectively. Because α is related to k , changing k by varying % B often results in changes in selectivity as well. Because the optimization of term iii of eqn [1] depends on the adjustment of % B , corresponding changes in selectivity (term ii) are conveniently made at the same time (by small further adjustments in % B). Note that acceptable values of

Table 3 Experimental conditions for initial isocratic HPLC separation

term iii can often be achieved by any value of %B within a 5–10% range. The ease of changing %B is a further reason for using this variable to vary selectivity.

Although selectivity is influenced by %B, changes in other conditions can have a much larger effect on values of α . Changes in the organic solvent type, pH, or use of additives are usually the next choice, once mobile-phase %B is optimized in terms of both k and α . For simplicity, we recommend changes in organic solvent first for neutral compounds. After starting with acetonitrile, change next to methanol, while reserving tetrahydrofuran as a last choice for solvent type. Changes in temperature can provide further changes in selectivity, especially for acid and base samples. If the sample contains acids and/or bases, changes in mobile-phase pH can be the most powerful means to control selectivity. If none of these approaches is successful, mobile-phase additives, such as ion-pairing reagents may be helpful, or a different kind of column (C₁₈, cyano, phenyl) can be tried.

Control of Column Efficiency

We have noted that sample resolution is not much increased by changes in column conditions (except for a large increase in run time). For the same reason, the column plate number N and term i of eqn [1] usually cannot provide a large increase in resolution, once terms ii and iii have been optimized. This means that it is important to select initial conditions which provide a value of N that will be sufficient for most separations. For most samples, we recommend one of the newer columns based on a low metal silica, often termed type B or base-deactivated silica. These columns reduce unwanted chemical interactions that cause peak tailing and column-to-column variations. Columns packed with spherical 5, 3.5 or 3 μm particles are preferable. We favour either (a) 150 \times 4.6 mm, 5 μm or (b) 75 \times 4.6 mm, 3.5 μm columns as a starting point. Column (a) is the first choice of many users because it is robust and has sufficiently low back pressure to allow operation at 2 mL min⁻¹, resulting in short run times. Smaller particles give a better compromise of plate number versus run time (for the same column pressure drop), but are more prone to problems such as blockage by particulates in the sample or mobile phase.

If the adjustment of conditions for optimization of terms ii (α) and iii (k) in eqn [1] has been successful, not infrequently sample resolution will be greater than required. In this case, run time can often be substantially reduced by increasing flow rate while decreasing column length. The latter represents the

most profitable use of term i (by change in column conditions).

Gradient Elution

Most workers prefer isocratic methods for routine use. If an isocratic separation is not feasible because of too broad a sample retention range ($0.5 < k < 20$ not possible for all peaks), gradient elution is required. Even where a final isocratic method is possible, it is still advantageous to begin the method development process with a gradient run. Thus, a single gradient run can be carried out which will provide an attractive value of term iii for every sample peak, thus avoiding problems in isocratic elution that are caused by values of %B that are too large or too small (poor resolution, long run times, wide peaks and poor detection sensitivity). With isocratic separation, several runs (and several hours) may be required to find conditions for which $0.5 < k < 20$ for the sample. In contrast, equivalent conditions for gradient elution can be determined in advance and the first run can generate a reasonable separation. Furthermore, by using method development software with gradient input runs, it is easy to convert a gradient method to an isocratic one and to evaluate the trade-offs between an isocratic and gradient final method.

Typical starting conditions for gradient elution are given in Table 4. In general, longer gradient times (smaller %B min⁻¹ changes) will give the same results (increased resolution and run time, broader and

shorter peaks) as using a weaker mobile phase (lower %B) in isocratic separations. The earlier discussion of the chromatograms of Figure 2 illustrated the effect of gradient time on the separation. For more detailed instructions in the use of gradient elution, consult the Further Reading section.

Method Development Strategies

The goal for method development is to obtain a robust method with acceptable resolution and run time. The strategy to reach this goal has two components. First, selectivity variables should be chosen for testing in an order that is most likely to give a successful separation in the minimum amount of development time. Second, for robustness in routine use and method transfer, the separation conditions should be as simple as possible and avoid potentially unstable parameters.

Most neutral or ionic samples can be separated successfully with reversed-phase columns and simple binary mobile phases of water or buffer in combination with one of the three primary organic solvents – acetonitrile, methanol or tetrahydrofuran. A choice of conditions should be made by investigating the parameter most likely to succeed, then moving to the next most likely, and so forth. If a satisfactory separation cannot be obtained by single-parameter optimization, the use of (simultaneous) two-parameter optimization can be explored.

Choice of Selectivity Variables

Selectivity variables should be examined one at a time in a systematic manner. Starting conditions generally will correspond to those listed in Table 3 or 4. Systematic method development can be approached by proceeding in order through the variables listed in Table 5, as described below.

Optimize %B First adjust the mobile-phase %B for reasonable *k* values and fine-tune for selectivity, as described previously. Acetonitrile is generally the first choice for organic solvent, but methanol is an accept-

Figure 4 Solvent nomograms for reversed-phase separations. Convert percentage acetonitrile (ACN) to percentage methanol (MeOH) or percentage tetrahydrofuran (THF) by moving vertically between scales.

able alternative. Use water as the A solvent for neutrals or a low pH buffer for ionics.

Solvent type If a separation cannot be obtained with acetonitrile, change to methanol and repeat the optimization experiments. A mobile phase that gives approximately the same retention time can be selected with the help of the nomogram shown in Figure 4. For example, 60% acetonitrile–water is roughly equivalent to 70% methanol–water. If neither solvent provides satisfactory separations, some workers will try tetrahydrofuran at this point, but we recommend delaying the use of this solvent until later. Tetrahydrofuran readily forms peroxides and is less desirable for other reasons.

Figure 5 illustrates both the use of the nomogram of Figure 4 and the selectivity that may be obtained with different organic solvents using simulated chromatograms of a 10-component steroid mixture on a C₁₈ column. Figure 5A shows the best separation with acetonitrile (50%); the resolution of the critical pairs is shown. Figure 4 indicates that 50% acetonitrile is equivalent to about 60% methanol, and the methanol separation is shown in Figure 5B. The separation in methanol is significantly improved, but still unsatisfactory, so tetrahydrofuran is tried next. Figure 5C shows the 40% tetrahydrofuran separation, with baseline resolution of all peaks. Note that the nomogram is not perfect – the indicated tetrahydrofuran concentration resulted in a longer run time than for acetonitrile or methanol.

Temperature Column temperature should be controlled so that retention times do not drift. In general, a 1–2% change in retention will be observed for a 1°C change in temperature, but many workers do not appreciate that selectivity also often changes with temperature. A second experiment run at 20–30°C higher temperature will indicate if improved selectivity can be obtained by varying column temperature. While changes in α as a result of a change in temperature are smaller than for other changes in conditions, this disadvantage is offset by the greater

convenience of a change in temperature, without any offsetting disadvantages.

Mobile-phase pH If the sample contains ionizable compounds (acids or bases), mobile-phase pH represents a powerful variable for changing selectivity. Thus, values of k for ionized species will generally be much smaller than for the nonionized compound. As a result, both absolute and relative retention for acids or bases can change dramatically with small changes in pH, when the pK_a value of the compound is within 1–1.5 units of the mobile-phase pH. Be sure to use buffers within their effective buffering range (± 1 unit from the buffer pK_a). When optimizing pH, changes in steps no more than about 0.5 pH units are recommended. Note that silica-based columns are generally limited for use at $2 < \text{pH} < 8$.

On the other hand, the choice of a $\text{pH} < 3$ is advantageous for several reasons: first, the pK_a values of both acids and bases will differ from the

mobile phase pH by > 2 units, so that sample retention will not vary with small changes in pH; i.e., the method will be more robust. Second, bases are usually best separated at low pH, because undesirable interactions between sample molecules and the column packing (i.e. silanols) are suppressed, thereby minimizing peak tailing and maximizing column plate numbers. However, the choice of a $\text{pH} < 3$ means that very little change in selectivity can be expected as a result of intentional changes in pH (e.g. for $2 < \text{pH} < 3$).

Column type The initial separation will usually be done on a C_8 or C_{18} column. For changes in selectivity, it is seldom fruitful to change the bonded-phase chain length (e.g. C_8 to C_{18} or C_4). Similarly, although changes in selectivity may be observed with the same phase obtained from different manufacturers, the magnitude of such changes is generally small. Rather, if the column is to be changed in order to change selectivity, it is recommended to change

to a stationary phase with significantly different chemistry.

After a C_8 or C_{18} column has been tried, a cyano (CN) phase is usually the next choice. Because cyano columns are more polar, similar retention requires the use of 10–20% less organic solvent; e.g. similar retention might be obtained with 35%B on a cyano column as with 50%B on a C_8 column.

A phenyl column is usually the next choice, if a cyano phase does not work. However, recently developed columns with an amide or carbamate function (e.g. Symmetry Shield, Zorbax Bonus RP or Discovery Amide) have proven to have unique selectivity that is also worth exploring when examining column-type effects. Additional information regarding column selection and chemistry can be found in the Further Reading section.

Additives Mobile-phase additives (in addition to buffers) can be used to enhance selectivity with some sample types. For example, ion pairing may be used to advantage when the sample contains both acidic and basic components. While large changes in selectivity are possible by varying the concentration of an ion pair reagent, ion pairing often results in long equilibration times when changing the mobile phase, as well as other problems. Optimization of additives is beyond the scope of the present discussion.

Tetrahydrofuran Tetrahydrofuran as the B solvent often gives significant selectivity changes when compared to acetonitrile or methanol. Problems related to slow equilibration, equipment memory effects, excessive UV background at low wavelengths, instability and unpleasant odour make most workers delay the use of tetrahydrofuran until it is unavoidable. In spite of these potential problems, tetrahydrofuran does have unique selectivity characteristics and will often provide separations when acetonitrile or methanol have failed. If tetrahydrofuran is to be used, use Figure 4 to select starting mobile-phase conditions based on previous experiments with acetonitrile or methanol.

Separation mode When efforts at obtaining a successful reversed-phase separation prove unsuccessful, one should consider other separation modes. Several other separation modes are shown in Table 2.

Single-Variable Optimization

Traditionally, a single variable is optimized at a time during HPLC method development. In most cases, one can proceed through the list of variables in

Table 5 in order, stopping when an adequate separation is achieved. A convenient procedure is to optimize the first variable, then hold that condition constant while changing the next parameter. This sequential optimization of parameters is a straightforward approach. Once all the desired variables have been optimized, it is a good idea to make small and reasonable changes around the final conditions to check robustness. For example, change ± 3 –5%B, ± 0.5 pH units, $\pm 5^\circ\text{C}$, and so forth to make sure the separation is not adversely affected by such changes.

Multi-Variable Optimization

An alternate approach to single-variable optimization is to change two or more parameters at once. Two different approaches are suggested: the method development triangle and the simultaneous optimization of solvent strength (or gradient time) with a second variable. In both of these cases, one should choose variables that change selectivity in different ways, ideally orthogonal to each other in terms of their selectivity effects.

Method development triangle The method development triangle shown in Figure 6 is a widely used approach for selecting the optimum organic solvent or mixture of organic solvents. This is a logical next step when acetonitrile, methanol and tetrahydrofuran have been optimized individually, and the least resolved peak pairs are different for at least two solvents. Each corner of Figure 6 represents a binary-solvent mobile phase with a %B value (for each of these three B solvents) that gives acceptable isocratic

Figure 6 Solvent selectivity optimization for reversed-phase HPLC. Experiments 1, 2 and 3 are binary (water and one organic) mobile phases; 4, 5 and 6 are 1:1 ternary (water and two organics) blends of corner compositions, and 7 is 1:1:1 quaternary (water plus three organics) blend of corner compositions.

separation; e.g. so as to give $k \approx 10$ for the last peak in each separation. These mobile phases (1, 2 and 3 in Figure 6) then are blended 1:1 or 1:1:1 for the remaining experiments. Once all seven experiments are run, the chromatograms can be spread out in the same grid pattern and examined for changes in selectivity between conditions. Further adjustments in solvent blends may be beneficial. For simplicity and robustness, mobile phases with fewer solvents are preferred (binary > ternary > quaternary). As with other optimization strategies, the final conditions should be varied in a systematic manner to determine the robustness of the chosen mobile phase.

Two-variable optimization The method development triangle approach (shown in Figure 6) is one example of the simultaneous variation of two variables. Other two-variable optimization procedures are now possible with the recent availability of appropriate computer simulation software. This new software (DryLab version 3.0, LC Resources) facilitates the simultaneous optimization of either isocratic %B or gradient time and any second variable (e.g. temperature, pH, additive concentration). The combination of two variables having different selectivity actions can help identify separation conditions that are unlikely to be found using more traditional approaches. With the use of optimization software, four to six input runs allow the user to model the separation under any combination of the two variables.

An example of the results of a two-variable optimization is shown in Figure 7 using a 150 mm C_{18} col-

Figure 7 Simulated chromatograms for separation of 10 benzoic acids and anilines using a 150 mm, 5 μ m particle C_{18} column with acetonitrile–buffer mobile phases. (A) Optimum separation at pH 3.0 (15% acetonitrile); (B) optimized %B–pH conditions (pH 3.4, 25% acetonitrile) using computer-assisted method development (DryLab).

Isocratic %B or gradient time versus any variable	4–9

umn with buffered acetonitrile to separate a 10-component mixture of benzoic acids and anilines. The best single-variable separation (at an arbitrary starting pH of 3.0) is shown in Figure 7A with $R_s > 2$, but the %B must be held within $\pm 1\%$ and the pH within ± 0.05 units to maintain $R_s > 1.5$, so the method is not robust. Using six experimental runs and computer optimization, the lower chromatogram (Figure 7B) was obtained, offering $R_s > 2$ for $\pm 5\%$ B and ± 0.1 pH units in half the run time.

Computer-Assisted Method Development

Many of the above changes in separation as a function of conditions can be described in theoretical or empirical equations. The fundamental relationships defined in eqn [1] form the basis of algorithms used to predict resolution. For example, term i of eqn [1] can be calculated from first principles, term ii is defined in eqn [3], and $\log(k)$ is linearly related to %B (term iii). This means that two experiments differing only in %B can be used to predict resolution at any other %B. Similarly, basic theory can relate isocratic and gradient separations in terms of the same retention relationships. A computer program (software) can therefore be used to predict separation as a function of isocratic %B, gradient conditions, and/or column conditions, using two gradient runs to calibrate the sample and initial conditions. The example of Figure 7 required six runs (3 pH values at each of two gradient times) for optimization of isocratic %B and pH. Some of the other variables available for optimization with one of these programs (DryLab® software) are shown in Table 6 along with the number of input experiments required. The use of optimization software is strongly recommended in order to reduce method development time, achieve more robust separations, and gain a better understanding of the separation.

Table 7 Common HPLC separation problems

Observation	Problem source	Solution
Poor peak shape	Wrong silica type Blocked frit or column void Silanol interactions	Use type B silica Replace frit, backflush column Use amine additives, change pH, use end-capped stationary phase
Excessive peak width	Bad column Column overload High molecular weight Unresolved peaks	Replace column Reduce injection volume or mass Normal
Inadequate retention	Mobile phase too strong Column too weak Samples ionized Samples too polar Gradient starting too strong	Improve separation Use lower %B Switch to C ₁₈ Change pH Change to normal phase Start at lower %B
Excessive retention	Mobile phase too weak Column too retentive Samples too hydrophobic Gradient stops too soon	Use higher %B Switch to C ₈ , C ₄ or CN Change to normal phase Stop at higher %B
Excessive retention range	Acids and bases or bases and neutrals in sample Too broad of polarity for isocratic method	Use ion pairing Use gradient elution
Inadequate resolution	Retention too short Poor selectivity Plate number too low	Increase <i>k</i> Change α Use longer column or smaller particle size

Troubleshooting Common Problems

Table 7 highlights some of the commonest causes of chromatographic problems likely to be encountered in the HPLC method development.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN SOLID-PHASE EXTRACTION

M. J. M. Wells, Tennessee Technological University, Cookeville, TN, USA

Copyright © 2000 Academic Press

Solid-phase extraction (SPE) is a sample preparation technique combining nonlinear modes of chromatography for the separation, purification, concentration and/or solvent exchange of analytes of

interest. SPE is the removal of chemical constituents from a flowing liquid sample via retention on a solid sorbent, and the subsequent recovery of selected constituents by elution from the sorbent. SPE was developed as an heterogeneous (two-phase) alternative to homogeneous (one-phase) liquid–liquid extraction (LLE) for the isolation of solutes from solution.

Background

The modern era of SPE began in October 1977 when prepackaged, disposable cartridges/columns containing bonded silica sorbents were introduced by Waters Associates. This technique was featured on the cover of *Laboratory Equipment* in May 1978 and the first peer-reviewed method was published in the *Journal of Chromatography* that same year. The term solid-phase extraction wasn't actually popularized until the early 1980s.

Unlike the meagre resources available to early SPE researchers, there are currently thousands of publications for analytes of pharmaceutical and environmental interest that may be consulted for examples of developed SPE methods. Many manufacturers publish bibliographies of methods developed using their products that are available in print or via the Internet. However, it is sometimes difficult to recognize the process used to arrive at published protocol, and, it is still common that an SPE method for the solute-matrix combination required has not been previously developed. Even if an appropriate method exists, it is advisable to understand thoroughly the principles of SPE method development in order to evaluate properly published methods.

Elsewhere in this volume, there are articles dealing with specific SPE topics (Table 1) that should be consulted for detailed descriptions. This contribution addresses method development issues in SPE.

Principles

SPE method development requires exploitation of analyte properties, selection of the appropriate

Figure 1 Solid-phase extraction consists of four basic steps: (A) conditioning, (B) retention, (C) rinsing and (D) elution. (A) Conditioning the sorbent prior to sample application ensures reproducible retention of the compound of interest (the isolate). (B) Squares, adsorbed isolate; circles, undesired matrix constituents; triangles, other undesired matrix components. (C) Triangles, rinse the columns to remove undesired matrix components. (D) Circles, undesired components remain; squares, purified and concentrated isolate is ready for analysis. sorbent and recognition of limitations imposed on the analysis by the sample matrix. The distribution of the analyte between the sample matrix and the sorbent in SPE is determined by physical and chemical properties of the analyte and the sorbent. The sample matrix can be manipulated to influence the distribution. In SPE method development, identification of the characteristic properties of the analytes of interest is a necessary first step before the sorbent can be selected or the sample matrix can be modified to effect the recovery.

SPE consists of a basic four-step approach (Figure 1):

1. Sorbent preparation or pre-wash: stationary phase conditioning;
2. Retention: analyte adsorption;
3. Sorbent post-wash: removing undesirable contaminants;
4. Elution: analyte desorption.

The four-step process can be as simple as this or may become more involved as one or more of these stages includes additional phases, such as selective adsorption or selective desorption. SPE method development can be tedious because the retention and recovery processes are interdependent. Retention and elution are confounded during method development because the overall analyte recovery is dependent upon both the retention efficiency and the elution efficiency. If the analyte is only recovered in part by an SPE technique, it will be initially unclear whether the problem lies with the retention process or with the elution process.

Because of this quandary, SPE method development can be approached in two ways. An iterative approach to protocol development emulating the classical analytical approach to change one variable at a time can be used. Retention parameters are held constant at selected values while optimizing the elution process (Table 2). Once elution is optimized, then the most favourable conditions for retention are determined. The procedure is repeated until the desired results are obtained.

Alternatively, a factorial experimental design approach to determine extraction efficiency is an efficient method development technique. Parameters important to SPE, such as sample pH, elution solvent strength, ionic strength of the sample, addition of organic modifier to the sample, elution by gravity or vacuum, sorbent retentivity, selection of sorbent mass, sample volume, elution volume and sample concentration, representing effects on both retention and elution, may be selected as factors that influence analyte recovery. The factors are usually tested at two or three levels. As a screening procedure, the factorial design can quickly pinpoint significant effects important to SPE. The objective of the factorial design approach is to obtain as much information as possible from few analyses.

Fundamentals

Stationary-phase Conditioning

Each different SPE sorbent requires conditioning or pretreatment in order to activate or prepare the sorbent to retain the analyte. Conditioning of hydrophobic stationary phases requires a two-step process of treatment with organic solvent followed by an aqueous wash. The conditioning solvent is prepared to mimic the chemistry of the sample matrix, that is, matching the pH and/or the ionic strength of the matrix. The volume of each conditioning solvent passed through the sorbent is usually about five times the dead volume of the sorbent. In addition to activating the sorbent, the conditioning solvent(s) also removes undesirable contamination potentially remaining in the sorbent during manufacture.

Retention

Originally, hydrophobic bonded-silica sorbents were the first materials introduced specifically for SPE, but currently, a suite of sorbents in varying formats are available with nonpolar, intermediate nonpolar/polar, polar, strong and weak anion and cation exchange, and steric exclusion (restricted access) properties. SPE sorbents are designed to retain analytes by a primary mechanism (Table 3) but often exhibit a secondary mechanism as well. For example, bonded-phase ion exchange sorbents primarily exhibit anionic or cationic exchange mechanisms but the analyte also experiences nonpolar interactions with the bonded ligand. Also, nonpolar bonded silicas exhibit a secondary polar interaction due to the silica backbone and unreacted surface silanol groups. Knowledge of the dual retention mechanisms encountered in SPE can work to the analyst's advantage. Mixed-mode sorbents (different ligands on the same sorbent) capitalize on dual retention mechanisms by design.

Understanding the mechanism(s) of retention and the selection of an appropriate sorbent depends on a thorough understanding of the character of the analyte. The solute properties of principal importance to retention by SPE are hydrophobicity, polarity and ionogenicity.

Unionized chemicals Many organic compounds are not ionized in water. An unionized organic compound is formed entirely of covalent bonds. SPE sorbent selection and recovery of unionized compounds is known generally to depend on the hydrophobicity of the analyte. The most widely measured parameter used to represent solute hydrophobicity is the octanol/water partition coefficient (K_{ow}), which is the ratio of the analyte concentration in octanol (o) relative to its concentration in an aqueous (w) phase. The logarithm of K_{ow} , also referred to as $\log P$, ranges from -3 to 7 for organic chemicals. Analytes with $\log K_{ow}$ values less than 1 are hydrophilic; analytes with $\log K_{ow}$ values greater than 4 are highly hydrophobic; analytes with $\log K_{ow}$ s between 1 and 4 are intermediate in hydrophobicity/hydrophilicity.

Aliphatic hydrocarbons and mono- and polycyclic aromatic hydrocarbons (PAHs) are nonpolar compounds that tend to increase in hydrophobicity ($\log K_{ow}$) with increasing molecular weight; that is, they tend to be more distributed in the organic, octanol phase, rather than in the aqueous phase. As oxygen- and/or nitrogen-containing functional groups are added to these compounds, they may (but not always) become more polar relative to the parent compound and would distribute more equally between the octanol and water phases, or even prefer to exist in the aqueous phase, thereby decreasing the value of $\log K_{ow}$.

Sorbents for extraction of unionized compounds fall into two general categories: nonpolar extraction sorbents and polar extraction sorbents, depending on the polarity of the functional groups present. Commercially available reversed-phase bonded-silica sorbents for SPE are produced in ranging polarities. The identity of the hydrocarbon covalently bonded to the silica gel backbone may be varied. Common nonpolar ligands bonded on the silica gel surface include aliphatic hydrocarbons of one, two, eight, or 18 methylene, cyclohexyl or phenyl groups. The greater the number of methylene groups in the aliphatic chain, the greater the hydrophobicity of the sorbent generated, i.e. $C_{18} > C_8 > C_2$. For nonionized compounds, the hydrophobicity of the analyte and the hydrophobicity of the sorbent selected for SPE are inversely related; that is, less hydrophobic sorbents are used for highly hydrophobic analytes; conversely, the most hydrophobic sorbents should be used for more polar analytes.

Bonded-phase silica sorbents are known to exhibit mixed-mode retention mechanisms due to silanolphilic (silanol) sites that remain on the sorbent after the initial hydrocarbon is bonded to the surface. The presence of silanol groups reduces the hydrophobic

character of the surface. Silanol groups on the surface of bonded silicas interact with electron-rich hydroxyl, carbonyl, nitrile and nitro functional groups in analytes. Some of the silanol groups on the surface may be masked by a subsequent reaction with a short chain hydrocarbon in a manufacturing process termed end-capping. Consequently, reversed-phase sorbents that are end-capped are more hydrophobic in character than those that are not end-capped. When a less retentive, less hydrophobic sorbent is desired, a nonend-capped product should be tested. Other polar sorbents are produced by adding oxygen- or nitrogen-containing functional groups such as cyano, hydroxyl or amino to the hydrocarbon bonded phase, or functionalized polymeric phases are produced to enhance polarity. Unmodified silica, alumina and Florisil sorbents are polar extraction sorbents.

Matrix additives influence retention in SPE. For many nonionized chemical compounds, increasing the ionic strength of the sample matrix by the addition of sodium chloride decreases analyte solubility in the sample matrix and increases adsorption on to the nonpolar sorbent via a 'salting-out' effect. Increased salt content in the sample matrix may also produce silanol masking. Silanol groups remaining on the surface can also be deactivated through ion pairing by the addition of masking reagents such as tetrabutylammonium hydrogen sulfate to the sample matrix.

Adding water-miscible organic solvents such as methanol or acetonitrile to the sample matrix reduces the surface tension of the sample matrix, thereby decreasing the retentiveness of highly hydrophobic compounds. The addition of salt to increase the ionic strength of the sample matrix and the concomitant addition of methanol to decrease surface tension can be useful in developing methods for samples having multiple compounds that vary widely in their hydrophobic character.

Ionized chemicals Organic chemical compounds that undergo ionization are comprised of derivatives of acidic organic alcohols, carboxylic acids or basic amine functional groups. Substances that ionize dissociate into their conjugate acid or base in aqueous solution. Ionizable compounds, including organic acids such as acetic acid or benzoic acid, and organic bases such as ethylamine or aniline, are weak electrolytes and are incompletely dissociated in water. The acid dissociation constant, K_a , expresses the ratio of ionized to unionized analyte; therefore, the greater the value of K_a (or the logarithm of K_a , the pK_a) the more ionized material is present. Just as in LLE, the dependence of SPE

recovery on sample pH is a function of the pK_a of the analyte.

The relative per cent of unionized analyte to that in the ionized form exhibits a pH-dependent dissociation that can be exploited by SPE methodology. The relative concentrations of dissociated and non-dissociated forms of ionizable analytes in aqueous solution are equal when the solution pH is equal to the pK_a . Therefore, in aqueous solution an organic acid is 99% unionized when the pH of the sample is two log units below the pK_a ; and it is 99% ionized when the pH of the sample is two log units above the pK_a . Two log units is a good rule of thumb for considering retention of ionizable compounds. However, if the sorbent (whether nonpolar, polar or ion exchange) exhibits primary or secondary, nonpolar van der Waals-type interactions, the overall hydrophobicity and size of the ionized form of the analyte can also have an effect upon recovery and influence the two log units generalization.

In SPE method development for ionogenic compounds, the decision to be made is whether to retain the analyte as the dissociated or the undissociated form. If a compound is ionizable, the extraction may be performed using ion exchange of the dissociated form. Alternatively, if the analyte can be converted to an undissociated form by ion suppression or ion pairing, then SPE can be conducted on nonpolar sorbents, as described in the earlier section on unionized chemicals.

Organic acids lose protons in aqueous solution, ionizing to form anions, and are retained on cation exchange sorbents. Organic bases gain protons in aqueous solution, ionizing to form cations, and are retained on anion exchange sorbents. Strong and weak ion exchange sorbents are available for SPE. Ion exchange sorbents developed for SPE retain analytes not only by ionic (electrostatic) attraction, but also through secondary van der Waals (nonpolar) interactions between the analyte and the atoms comprising the bridge that links the charged functional group to the silica gel backbone.

Ion suppression refers to adjusting the pH of the sample matrix to influence the chemistry of the analyte of interest. If the ionizability of the analyte is suppressed by controlling the pH of the sample matrix relative to the pK_a of the analyte, then the analyte can be retained in the unionized form and nonpolar or polar extraction sorbents are used instead of ion exchange sorbents.

Ion pairing involves using a reagent added to the mobile phase to accomplish two objectives: to neutralize the analyte charge by combining with an oppositely charged counterionic solute; and to use a hydrophobic, bulky group on the counterion to

form an ion pair that is hydrophobic enough to be retained on nonpolar extraction sorbents. The ion-pairing strategy applies to ionized organics as well as metal cations.

Ionizable and nonionizable compounds may co-exist in the same sample to be analysed. Selective adsorption of either type of chemical in the presence of the other can be accomplished by controlling the sorbent through a mixed-mode approach or by chromatographic mode sequencing (the use of differing SPE sorbents in tandem), such as using both ion exchange and nonpolar mechanisms to extract the analytes. The use of selective adsorption can be applied to compounds differing in hydrophobicity, charge and structure.

In tandem mode, ionizable and nonionizable compounds may be fractionated by adsorbing nonionizable analytes on nonpolar extraction sorbents and ionized analytes on ion exchange sorbents. Once retained on different sorbents in tandem, they can be physically separated and eluted individually, thereby separating the compounds. Such fractionation often improves the ease of subsequent chromatographic analyses.

Selective adsorption of nonionized compounds in the presence of ionogenic compounds can also be accomplished with pH control of the sample matrix. By selecting a sample pH at which ionogenic compounds exist in the ionized form, it may be possible selectively to retain either the ionized or the nonionized components depending on the type of sorbent selected.

Values for hydrophobic parameters ($\log P$) and acid dissociation constants (pK_a) can often be obtained from the analyte's manufacturer. Alternatively, they can be measured in the laboratory or predicted by numerical estimation methods.

Sample volume and sorbent mass SPE retention is dependent on the relationship between sorbent mass and sample size. The strength of the interaction (whether nonpolar/polar or ion exchange) between the analyte and the sorbent, as influenced by the sample matrix solvent strength, determines the amount of the sample that may be passed through the sorbent before analyte breakthrough occurs. As the strength of the interaction increases and as the sorbent amount increases, the breakthrough volume increases. Breakthrough can be controlled and monitored by attaching a second check cartridge in tandem with the primary extraction cartridge, and eluting them separately.

To establish the dependence of retention on sample loading volume, variable volume samples (each of which comprises a constant molar amount loaded)

are passed through a constant sorbent mass and per cent recovery is plotted as a function of sample loading volume. Repeating this procedure for different sorbent masses will establish the dependence of retention on sorbent mass. Factorial design experiments can also be used to screen for the sorbent mass required relative to sample size. Optimizing the amount of sorbent necessary for the analysis will control analytical costs.

Adsorbed Contaminant Removal

During the retention process, undesirable contaminants in the sample matrix may become associated with the sorbent, or may remain behind in the interstitial spaces between sorbent particles. When the post-wash solvent is identical to the conditioning solvent and to the sample matrix, adsorbed contaminants are not likely to be removed. However, matrix components remaining in the interstitial spaces between sorbent particles will be flushed from the sorbent. The volume of the post-wash solvent should be at least equal to or preferably twice the void volume of the sorbent to ensure that the pore space is entirely replaced with the desired solvent.

If a blank, i.e. uncontaminated, sample matrix is available, it can be used to screen for potential column post-wash solvents. To remove undesirable contaminants in the sample matrix that became associated with the sorbent during the retention process, solvents of greater eluotropic or eluting solvent strength than the conditioning solvent must be used. Even a small amount of the elution solvent can be a post-wash solvent if the effects on the retained analytes of interest are monitored.

Elution

Elution solvent strength and volume The ability of a solvent to overcome the interaction between the analyte and a chromatographic sorbent, thereby causing elution to occur, is known as the solvent's eluotropic strength. Charts of eluotropic series can be consulted to determine relative solvent strength, which is roughly equivalent to polarity. The eluotropic strength of elution solvents on a non-polar adsorbent (e.g. reversed-phase) increases in reverse order to that measured on polar sorbents such as silica or alumina. On reversed-phase sorbents, the eluting power increases as the solvent polarity decreases.

Many different solvents are used for elution of the analytes from sorbents in SPE. Elution by acetic acid, methanol, acetonitrile, acetone, ethyl acetate, diethyl ether, methyl-*tert*-butyl ether, methylene

chloride, benzene and hexane, and aqueous buffers containing appropriate counterions have been reported. Miscible solvent mixtures produce elution solvents of intermediate eluotropic strength.

After candidate elution solvents are selected, an elution solvent screen is conducted. Elution solvents tested at a constant volume are compared for potential to elute the analytes of interest. When selecting a desorption solvent, the effect it will have upon contaminants adsorbed from the sample matrix must be considered. A control sample matrix should also be screened if possible. The solvent demonstrating the most desirable results in the elution screen is further examined for the variation of recovery as a function of the volume of eluting solvent. Generally, the elution solvent selected is the one for which the smallest volume produces acceptable recovery. However, elution with a larger volume of lower eluting strength solvent can have the advantage of leaving strongly retained contaminants on the sorbent as the analyte of interest is desorbed. Solvent selection must also be compatible with the analytical instrumentation used for final analysis.

The elution solvent screen may reveal that selective desorption is possible for an analysis. Selective desorption uses differences in the eluotropic strength of the elution solvents to produce serial desorption. Class separation or distinct fractionation of analytes may be possible if the chemical properties of the analytes differ enough that they respond differently to weak and strong elution solvents.

Elution rate The rate of elution can affect the SPE recovery of solutes from the sorbent. Particularly for highly hydrophobic compounds, there can be slow mass transfer from the stationary phase into the mobile phase. The problem can be overcome by reducing the flow rate during elution, even to the point of allowing elution to occur by gravity if necessary.

Sample concentration independence Finally, any protocol developed must be independent of sample concentration in the range of samples to be analysed. Care must be taken not to exceed the maximum loadability of the sorbent, but that is generally not a problem since SPE is primarily used for trace enrichment.

Applications

Early in SPE history, a series of simple yet ingenious experiments were developed by Bidlingmeyer and Warren that illustrate the principles of SPE. This author has used these experiments as practical demonstrations to introduce SPE method development to

Table 4 SPE isolation of food colours in grape drink

new users from elementary school students to adult analysts. These experiments are outlined here (Table 4) as practical applications of the foregoing discussion. They are a useful method development learning aid for novice users because:

1. they demonstrate the four-step process of SPE;
2. the dyes concentrated and separated in these experiments can be observed by the naked eye, clearly revealing extraction and recovery processes;
3. the stepwise recovery of dyes from the sorbent demonstrates the ability of SPE selectively to fractionate samples.

The experiments, A–F in Table 4, demonstrate the use of SPE to isolate food colours using inexpensive reagents. The analytes in these experiments are the dyes FD&C Blue 1 and FD&C Red 40 prepared in an aqueous mixture by dissolving grape-flavoured drink mix (Kool-Aid®), in distilled water. Other reagents necessary for these experiments include vinegar, rubbing alcohol and mouthwash. The original source (Bidlemyer and Warren) should be consulted for details.

The types of sorbents used for the experiments are a hydrophobic, reversed-phase sorbent, C₁₈ (experiments A–C), and a polar sorbent, silica (experiments D–F). The same two analyte dyes are retained in each experiment, albeit via different mechanisms depending on the sorbent: by van der Waals forces on the C₁₈ sorbent and polar dipole–dipole interactions with the silica sorbent.

On the reversed-phase sorbent (C₁₈), conditioning involves exposure of the sorbent to a water-miscible

organic solvent followed by an aqueous wash (experiments A–C). The preparation of the sorbent surface to accept the analyte must be done in this order. Measuring exact amounts of solvents is not necessary during the pre-wash step. The sorbent is not allowed to dry between column preparation steps and the sample loading step. If it does dry out during column preparation, before the sample has begun to be loaded, the process should begin again. The silica sorbent is activated by a single aqueous pre-wash of water (experiments D and F) or distilled white vinegar (experiment E).

As the sample is loaded on to the sorbent, the organic dyes extracted are observed to become concentrated at the leading edge of the sorbent. After the sample is loaded, drying of the column is not crucial, and in fact it is useful in some analyses to dry the sorbent with vacuum before eluting the analytes.

FD&C Blue 1 (Brilliant Blue FCF, CAS # 3844-45-9) and FD&C Red 40 (Allura Red AC, CAS # 25956-17-6) are large dye molecules (formula weights of approximately 800 and 500, respectively) that have negatively charged sulfonate groups in aqueous solution. Although ionogenic, the molecular size and hydrophobicity of the dyes permit retention on the C₁₈ sorbent even without pH control (experiments A and B).

Two of the experiments demonstrate the effect of matrix additives on retention (experiments C and E). In experiment E, distilled white vinegar is used for ion suppression by reducing the pH and its addition results in reversal of the elution order of the dyes. In experiment C, an ion-pairing reagent, cetylpyridinium chloride (Cepacol® mouthwash), is added as

a bulky, hydrophobic, positively charged counterion to pair with the negatively charged sulfonate groups of the dyes. In this case, cetylpyridinium chloride also behaves as a silanol masking agent.

Post-washes flush any remaining sample matrix from the interstitial pores of the sorbent, and in each experiment the post-wash solvent is the same as the last pre-wash solvent. Additives in the drink mix that are not retained (sugars, acids) will elute during sample loading and during the post-wash.

Elution is accomplished by varying the concentration of isopropyl alcohol (commercially available rubbing alcohol is approximately 70% isopropyl alcohol in water). The isopropyl alcohol is mixed with either water (experiments A, B, C, D or F) or vinegar (experiment E). Sample desorption volumes are measured for quantitative purposes. The volume recovered is always less than the volume added. The desorption can be done in one isocratic separation process (experiments A, D and E). Performed in stages, experiments B, C and F are examples of selective desorption. SPE columns generate around 20–200 theoretical plates and this is sufficient in many cases to produce a fractionation of components and chemical classes.

Future Developments

The history of SPE has already been marked by continuous advances in sorbents and the formats in which SPE sorbents are utilized. So, it's a fairly safe prediction that in the future there will be continued development of new SPE sorbents and modes of delivery. Along that trend, recent developments of molecularly imprinted sorbents for SPE and the 96-well plate format for SPE are gaining attention and are expected to be actively developed in the near future. Molecularly imprinted sorbents for SPE are polymeric phases formed with the analyte of interest as a print molecule. The template thus formed exhibits selectivity for the imprinted molecule. The 96-well microassay plate collection format is designed to utilize robotics for simultaneous extraction of 96 samples.

In addition to continued development of specialty-phase sorbents and formats, advances in performing more sophisticated chemistry associated with extraction are predicted. Applications of analyte derivatization in conjunction with SPE are already reported, with the chemical reaction occurring at the sorbent surface. Methods apply either to solid-supported reactants or solid-supported analytes. Selective adsorption schemes that utilize tandem chromatographic mode sequencing approaches will be used to solve complex multiclass/multiresidue extractions. More intricate mixed-mode adsorption mechanisms that

mimic analyte–receptor ‘lock-and-key’ approaches to extraction are expected.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN SUPERCRITICAL FLUID CHROMATOGRAPHY

P. Schoenmakers, Shell Research and Technology Centre (SRTCA), Amsterdam, The Netherlands and University of Amsterdam, Amsterdam, The Netherlands

Copyright © 2000 Academic Press

Introduction

Supercritical-fluid chromatography (SFC) is defined as a mode of chromatography in which both the temperature and the pressure in the column exceed the critical values of the mobile phase. This definition is exact, but rather arbitrary, as there is no phase transition between gases (or liquids) and supercritical fluids. Technically, a gas chromatograph operated above 2.24 atm with He as the carrier gas, is an SFC instrument according to this definition. We normally speak of gas chromatography when retention is largely controlled by the oven temperature (and largely determined by analyte volatility). We speak of SFC when retention is largely controlled by the mobile-phase density (and largely determined by analyte interaction with the mobile phase). Supercritical-fluid chromatography (another name for it is dense-gas

chromatography) was first developed in the 1960s by Klesper in Aachen, shortly followed by Sie and Rijnders in Amsterdam. The technique subsided into oblivion during the rapid advent of modern high pressure liquid chromatography (HPLC) in the 1970s. It experienced a second youth in the 1980s. During this period, some researchers optimistically claimed that SFC combined the advantages of gas chromatography (GC) and HPLC. Although statements of this kind still appear in the literature today, the chromatographic community as a whole has come to accept that SFC holds a position somewhere in between, rather than above GC and LC. SFC offers an – occasionally favourable – compromise between the two mainstream chromatographic techniques (see Table 1).

Why opt for SFC?

Although this article deals specifically with SFC, we are treating it as a niche technique. In real life, GC and HPLC are more commonly available. When GC can readily be used, SFC offers few advantages other than a lower operating temperature. When

Table 1 General considerations when considering SFC as a possible chromatographic separation method*

Parameter	GC	SFC	LC
(Most) suitable application range	Gases and volatile materials All but the most polar analytes	Low to marginally volatile materials Low to moderately polar analytes	Low-volatile and non-volatile materials All polarities (non-polar to ionic)

**Feasible, but highly corrosive.

***Highly corrosive and hardly feasible.

HPLC may readily be used, SFC – when applicable – may offer shorter analysis times and a greater choice of detectors. HPLC can be applied to a much greater variety of samples and analytes than SFC.

Table 1 lists some general considerations for considering or discarding SFC as a possible (analytical) separation technique. The most important reasons for selecting SFC are described below in more detail.

Universal detection When using carbon dioxide (CO₂) as the mobile phase, SFC allows the use of flame-based detectors (see Table 2). The flame-ionization detector can be applied almost universally. Even more importantly, it shows an approximately equal response within a class of analytes. As a result, reference standards within each class (rather than for each individual compound) suffice for calibrating a quantitative method.

Because universal detectors are available in GC, but not in LC, there are potentially, two directions in which relevant SFC–FID methods can be developed:

- analysis of non-volatile materials, that cannot be analysed by GC (including the high-temperature version, HT-GC); and
- achieving separations with a (type of) selectivity that cannot be achieved in GC.

Applications in the former direction are quite rare. Some thermally labile components, such as explosives and peroxides, have been analysed by SFC. However, due to the highly inert nature of GC mobile phases (e.g. helium), the increased inertness of modern GC columns, and the increased flexibility of injection systems (e.g. cold on-column injection), such components can often be analysed with good integrity by GC.

Some components that are not sufficiently volatile for analysis by HT-GC may be amenable to analysis by SFC. However, in the author's experience this is limited to highly apolar materials, such as saturated hydrocarbons. For moderately polar analytes, such as aromatic hydrocarbons, HT-GC appears to allow materials with higher boiling points (lower volatility) to be eluted in comparison with SFC.

The most successful SFC–FID methods follow the second approach, using a unique kind of selectivity. In GC, retention is determined by two factors, viz. the pure-analyte vapour pressure and the interactions of the analyte with the stationary phase. In SFC the effect of the vapour pressure can be minimized by working with high-density mobile phases, while the interaction with the stationary phase can be maximized by using stationary phases with large, active surface areas. This allows a so-called 'group-type selectivity' to be achieved, in which the sample is separated (or classified) into a limited number of distinct groups (or classes) of analytes. Within a class, the size (and thus volatility) of the analyte molecules varies, but the chemical structure (functional groups) remains similar. Examples of such methods include the following.

- Separation of complex hydrocarbon mixtures, for example the separation of middle-distillate fuels (diesel or kerosene) into saturates, mono-aromatics and di-aromatics; the determination of the total amount of olefins in gasoline-type fuels. Both these examples concern highly successful applications of SFC. A group-type separation method for middle distillates is standardized as ASTM D-5186. An ASTM standard method for olefins in

gasoline by SFC is expected to be approved by June 2000.

- Separation of (low-molecular-mass) polymers into fractions representing different end-groups.

In both cases, we try to achieve retention that is affected by the chemical structure of the molecules (the *functionality*) but irrespective of their size (molecular mass). This type of chromatography is – somewhat confusingly – referred to as ‘critical chromatography’, or as ‘supercritical-fluid chromatography at the critical conditions’.

Difficult separations SFC possesses some favourable fundamental characteristics, especially in comparison with liquid chromatography. The molecular diffusion is about an order of magnitude greater than in liquids (but three orders worse than in gases) and the viscosity is about a factor hundred lower than that of a typical liquid. Thus, SFC has advantages in terms of mass transfer and column pressure drop. This may result in higher efficiencies per unit length of column, while longer columns may sometimes be used. Therefore, SFC may be attractive for some difficult separations.

SFC has proved a rather attractive alternative to normal-phase LC for the separation of stereoisomers. Like in normal phase LC, CO₂-based SFC features a polar stationary phase and a non-polar mobile phase. Organic modifiers may be added to modify the mobile-phase polarity and detergent-like molecules have been added to help create adequate selectivities. The advantages of SFC in this context are summarized in Table 3.

SFC is seen to score well in all categories, except its flexibility in dealing with a variety of samples. Reverse-phase LC (RPLC) also scores well in the table. SFC appears to be more attractive as an alternative to normal-phase LC (NPLC) than to RPLC. The latter technique is compatible with almost all sample sol-

vents, ranging from water to quite non-polar organic solvents, such as tetrahydrofuran. NPLC on unmodified silica surfaces can be used in combination with solvents of low-to-medium polarity. When using polar-bonded phases, again a great variety of sample solvents may be introduced on the column. In both cases (RPLC and NPLC), strongly acidic and strongly basic samples cause problems. SFC is typically restricted to solvents and analytes of low to moderate polarity, especially in case FID detection is to be used.

Preparative separations Carbon dioxide is an outstanding solvent for preparative chromatography. It is available in high purities at a relatively low cost and it can easily be removed from the effluent by evaporation. In fact, the latter characteristic implies that it is somewhat more difficult to collect fractions than is the case in preparative LC.

The main disadvantage of CO₂ for preparative chromatography is its low polarity, which seriously limits its applicability as a chromatographic eluent. Packed columns, with large surface areas and thus high sample capacities, are desirable for preparative separations. Without organic modifiers, only components of little or no polarity can be eluted from such columns using CO₂. When substantial amounts of modifiers need to be used, the advantages of using CO₂ diminish.

Hyphenated systems

SFC–MS Although it would seem that the use of CO₂ is also advantageous when coupling a dense-phase chromatograph to a mass spectrometer (MS), successful SFC–MS systems have hardly materialized. In what are now the most common LC–MS interfaces (electrospray, ESI; and atmospheric-pressure chemical ionization, APCI), a high mobile-phase polarity is preferable. Only a small niche remains where

Table 3 General advantages of (packed-column) SFC in comparison with reversed-phase (RPLC) and normal-phase (NPLC) liquid chromatography*

Property	Related to:	RPLC	SFC	NPLC

*Most important effects are in italics.

**Very high plate numbers have been reached in SFC but operating conditions close to the critical point must be avoided.

SFC-MS may compete with LC-MS, i.e. components of low volatility and low polarity. This implies that there is little incentive for the further development of SFC-MS.

SFC-NMR CO₂ is a perfect eluent when ¹H-NMR is to be coupled with a chromatographic separation device. LC-NMR has received a good deal of attention in recent years and some workers have extended this work to include SFC-NMR. The main instrumental difference is that a high-pressure flow-cell (or 'probe') is required. However, the inherent sensitivity of NMR is so low that fractionation followed by offline spectroscopy is usually the preferred approach.

SFE-SFC Very elegant hyphenated systems may arise from a combination of two separation techniques that both involve supercritical fluids. Such systems include SFC-SFC and SFE-SFC. The latter approach, where the extraction serves as an online sample-preparation technique, has been especially investigated by several groups. Unfortunately, the high expectations surrounding SFE around 1990 have not quite materialized. Current interest in SFE-SFC has waned.

Types of SFC Columns

There are traditionally two approaches to SFC. One involves packed columns, the other open-tubular (capillary) columns. This situation is not different from that experienced in GC and LC. In the former technique, open columns are strongly preferred. In the latter, open columns are ideal in theory, but virtually impossible to use in practice. The optimum internal diameter of open columns used in chromatography is essentially determined by the diffusion coefficients of the analytes in the mobile phase. As a rule of thumb, the required analysis time is given by

$$t_R = \frac{N_{\text{req}} b d^2}{v D_m} (1 + k)$$

where t_R is the required analysis time for a separation with N_{req} theoretical plates and a solute retention factor of k , b is the reduced plate height, d the column diameter, v the reduced (average) velocity and D_m is the diffusion coefficient of the analyte(s) in the mobile phase. Both N_{req} and k are essentially determined by the retention of the analytes. The greater the selectivity (differences in retention), the lower the required number of plates. Neither

N_{req} nor k are affected by the dimensions (length and diameter) of the column. The reduced plate height (b) and the reduced (average) linear velocity (v) have typical values for packed and open-tubular columns. Typically, for packed columns $b = 3$ and $v = 10$, so that $b/v = 0.3$. For open-tubular columns $b = 4.5$ and $v = 45$ are good values, so that $b/v = 0.1$. All things being equal, open-tubular columns are expected to be about three times faster than packed columns.

D_m is the parameter that suggests SFC may allow faster separations than HPLC. However, the diffusion coefficient must be balanced against the characteristic dimension (d) of the column. For packed columns, d is the particle diameter (d_p), while for capillary columns it is the internal diameter of the column (d_c). It follows from the equation that similar performance (in terms of analysis times) can be expected in different forms of open-tubular chromatography when the ratio d_c^2/D_m is kept constant. With $D_{m,\text{gas}} \approx 1000 \times D_{m,\text{SF}} \approx 10^4 \times D_{m,\text{liquid}}$ we find for the optimum diameters of open tubular columns $d_{c,\text{GC}} \approx 30 \times d_{c,\text{SFC}} \approx 100 \times d_{c,\text{LC}}$. Since GC columns have internal diameters between 100 and 500 μm , we anticipate optimal internal diameters for SFC columns to be of the order of 10 μm and for LC columns to be 1–5 μm . Because very many practical problems are associated with the use of such extremely small columns, open-tubular SFC (OT-SFC) has typically been performed with somewhat larger columns (50 or 100 μm). However, this has led to a modest efficiency and speed.

Table 4 provides a summary of some of the advantages and disadvantages of using packed and capillary columns in GC and LC, with a more extensive summary of the characteristics of packed and open-tubular SFC. In SFC, open-tubular columns with optimal diameters are difficult to use. As a result, packed-column SFC is the more robust and more practical technique.

Most Important Parameters

The parameters that are most important in the development of SFC methods are as follows.

Mobile-Phase Density

The outstanding parameter in SFC is the mobile-phase density. This factor plays a role similar to the temperature in GC and the solvent strength in LC. Density gradients (typically increasing density linearly with time) in SFC are the common equivalent of temperature gradients in GC and mobile-phase composition gradients in LC. When the density increases,

Table 4 Advantages (↑) and disadvantages (↓) of packed and open-tubular (capillary) columns in GC, SFC and LC

	GC	SFC	LC
<i>Packed columns</i>	↑ Fast analysis ↑ Large sample capacity ↑ Broad dynamic range ↑ Reliable and robust ↑ Allows preparative separations ⇌ Perceived to be old-fashioned ↓ Low permeability ↓ Limited maximum efficiency	↑ Compatible with back-pressure regulators ↑ Broad range of optimum k values ↑ Programming often not needed ↑ Fast analysis ↑ Large sample capacity ↑ Broad dynamic range ↑ Reliable and robust ↑ Easy online solvent mixing ↑ Routine loop injections ↑ Allows preparative separations ⇌ Columns optimized for LC ↓ Low permeability ↓ Limited maximum efficiency ↓ High pressure drop ↓ Active stationary-phase surface ↓ Modifiers often required ↓ FID often not possible	↑ Compatible with many detectors ↑ Fast analysis ↑ Large sample capacity ↑ Broad dynamic range ↑ Reliable and robust ↑ Allows preparative separations ⇌ Columns still not perfect ↓ Very small particles required ↓ Low permeability ↓ Limited maximum efficiency ↓ High pressure drop
<i>Open-tubular columns</i>	↑ High permeability ↑ High maximum efficiency ↑ Inert surface for polar analytes ⇌ Many different injectors ↓ Limited sample capacity ↓ Limited dynamic range ↓ Sensitive to (large volumes of) solvents ↓ Sensitive to (liquid) water	↑ Inert surface for polar analytes ↑ Modifiers not often needed ↑ FID can usually be used ↑ High permeability ↑ Low column pressure drop ↑ High theoretical efficiency* ⇌ Very low mobile-phase flow rates ↓ Very small diameters required ↓ Sub-optimal (too large) columns commonly used ↓ Little tolerance for extra-column dispersion ↓ Very small sample volumes ↓ Proper injections are difficult (very small volumes and time splitting) ↓ Rather high detection limits ↓ Very small dynamic range ↓ Hard to combine with MS ↓ Narrow range of optimum k values ↓ Sensitive to (large volumes of) solvents ↓ Programming usually required ↓ Requires fixed restrictor (no adequate flow control)	↓ High permeability ↑ High maximum efficiency ⇌ Extremely low flow rates ↓ Very few detection options ↓ Extremely small diameters required ↓ Extremely small sample volumes ↓ High detection limits ↓ Extremely small dynamic range ↓ No tolerance for extra-column dispersion

*In practice, the efficiencies obtained in open-tubular SFC are well below the theoretically expected values.

interactions between the mobile phase and the analytes increase. The analytes are better dissolved in the mobile phase. Retention typically decreases exponentially with increasing density.

The column inlet and outlet pressures are significant parameters, but their effect on retention is indirect, as the pressure affects the density. In this context, the pressure closest to the critical value is most important. In SFC this is the column-outlet pressure.

Pressure, temperature and density are connected through an equation of state. Different equations can be used that provide good estimates for the density of pure supercritical fluids. However, when mixed eluents are used (e.g. CO₂ with a modifier such as methanol), no reliable equation is available that provides the density as a function of pressure and temperature. Nevertheless, when the latter two parameters and the composition of the eluent are established, the density is in principle defined.

Temperature

The second most important parameter is the temperature. Like the pressure, the temperature has a significant effect through its effect on the density. However, at constant density, an increased temperature may lead to a lower retention, especially for relatively volatile analytes. Apart from the temperature of the column oven, the temperature of the injector or injection valve can also be quite significant. In order to test the feasibility of eluting certain analytes by SFC, it is worthwhile to perform some experiments at an increased injector temperature.

Stationary Phase

The stationary phase. The column used plays a major role in SFC, especially when using non-polar mobile phases, such as carbon dioxide. The stationary phase has a large effect on the retention and an often prevailing effect on the selectivity. In addition, the stationary phase has a very large effect on peak shape and peak width (efficiency). Again, this effect is strongest when using non-polar eluents (CO₂).

Studying the effects of different stationary phases can be (very) expensive and time consuming. There are often practical limitations and when the option to use modifiers is available, this may be attempted first, provided UV detection is adequate.

Mobile-Phase Composition

The mobile-phase composition may have dramatic effects on retention, selectivity, efficiency and peak shape in SFC. However, adding modifiers has some significant disadvantages, especially with regard to detector compatibility. Therefore, changing the mobile-phase composition is not the first option in developing an SFC method. There are two modifiers that allow FID detection to be used, i.e. water and formic acid. Both have been investigated, but neither has found many applications in practice. The effect of a modifier tends to be greatest at low concentrations. In this range, the modifier mainly acts by competing with the analytes for strong adsorption sites on the stationary-phase surface. A small amount of modifier (often well below 1%) may lead to a much reduced analysis time and a much increased column efficiency. The use of modifiers often leads to much sharper and much more symmetrical peaks. At higher concentrations, modifiers may still affect retention and selectivity, through increasing the polarity and the density of the mobile phase. However, these effects are much smaller and the variations become more gradual. At these high concentrations it is more likely that different modi-

fiers give rise to substantially different selectivities.

Method Development

The flow chart for developing an SFC method shown as Figure 1 follows logically from the discussion on different types of columns and the overview of main parameters given in previous sections above.

Carbon dioxide will almost always be the eluent of choice. This is assumed to be the case in Figures 1 and 2. Instrument availability is the obvious first consideration. It greatly affects all the other decisions taken. Selecting packed columns is very attractive (see Table 4), but this requires a compatible instrument, with a pumping system capable of delivering substantial flow rates. It is quite possible to use microbore (1-mm i.d.) and packed-capillary (≤ 0.5 mm i.d.) in SFC, but some of the advantages of packed-column SFC are then lost. Most importantly, miniaturized columns do not allow the use of controllable back-pressure regulators. In this case, there is no adequate flow control, a problem that is especially serious when the mobile-phase density (in practice the pressure and/or the temperature) is programmed during the run.

When a novel sample is being subjected to SFC, the recommended strategy is to rapidly establish

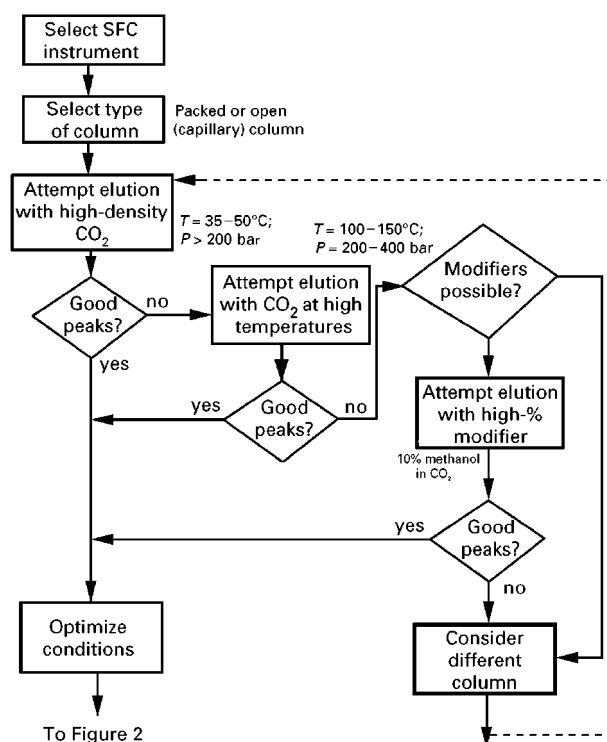

Figure 1 Flow chart for the development of an SFC method.

whether the analytes can be eluted. Because retention decreases with increasing density, high densities must be tried first. Once sharp peaks have been obtained for the analytes it will be easy to increase the retention by lowering the density. In open-tubular SFC a mobile-phase density gradient with a high final density will typically be used. In packed-column SFC, where retention times are typically of the order of minutes, constant elution conditions (isobaric, isothermal, isochoric and isocratic) will be preferred for initial scanning experiments.

Despite the high praise for FID, it is extremely valuable to have an informative detector available at this stage. A UV detector, especially a multichannel diode-array (DAD) instrument, will provide much on-line information on the progress of the method development. It is very much easier to know the whereabouts of different analyte peaks in the chromatogram if DAD and FID data are obtained simultaneously. In open-tubular SFC, a DAD cannot be used and SFC-MS is the obvious choice. However, SFC-MS is not an easily accessible practical tool.

If the analytes cannot be eluted at the highest possible (or highest practical) CO₂ density, it may yet be worthwhile to attempt elution at elevated temperatures. Increasing the temperature may lead to lower densities, but this may be compensated by an increased analyte volatility, especially for analytes with a significant vapour pressure. In addition, adsorption effects (including analyte-stationary-phase interactions) may be reduced. The temperature of the injector plays a different role. Sometimes it has proven beneficial to inject at temperatures well above the column temperature. In many cases, the sample (or sample solvent) is a limiting factor. When loop injection is used, the temperature must usually be kept well below the boiling point of the solvent.

If the analytes are not eluted as sharp, symmetrical peaks at high densities, nor at increased temperatures, then the use of modifiers may be attempted if this is an option. Using pre-mixed CO₂-based mobile phases is not attractive for reasons of accuracy and reproducibility as the composition in the cylinder will vary with time. Also, the flexibility regarding the possible concentrations is very limited. However, this is often the only choice in miniaturized (open-tubular) systems. In some cases, mixtures have been prepared inside the pump head of a syringe pump, which is preferred in terms of accuracy and flexibility. Many packed-column SFC systems allow more convenient online mixing, which makes it relatively easy to investigate the possible advantages of using modifiers. Unless experiments are performed with water or formic acid as a modifier (neither being very practical), the

use of FID is not feasible at this point. It may be useful to attempt a few different modifiers. However, the chances of obtaining good peaks become very small once the addition of 10% methanol has proven inadequate for the purpose.

The scanning experiments suggested so far can typically be performed within one or two days. This is what is referred to when it is claimed that method development in SFC can be very rapid. If at this stage the results are unsatisfactory, an important decision needs to be made. It is quite possible that better results will be obtained on a different column. However, when it is decided to investigate the use of different columns the amount of work needed will be multiplied. If there are still good reasons to opt for SFC, then it is most realistic to identify the column with the most inert surface (for example, a column packed with polysiloxane-coated particles) and repeat the sequence outlined above. If this attempt is not successful, then an alternative separation technique must be seriously considered.

Method Improvement and Troubleshooting

If at any stage during the method development rapidly eluting, sharp peaks have been obtained for the analytes, then the separation can be optimized. The actions that may be taken are summarized in Figure 2.

From the initial results it may be concluded whether the retention should be increased. The appropriate action depends on the stage at which success was obtained. If high-density CO₂ at a low temperature proved successful, then reducing the density will suffice. When elevated temperatures were

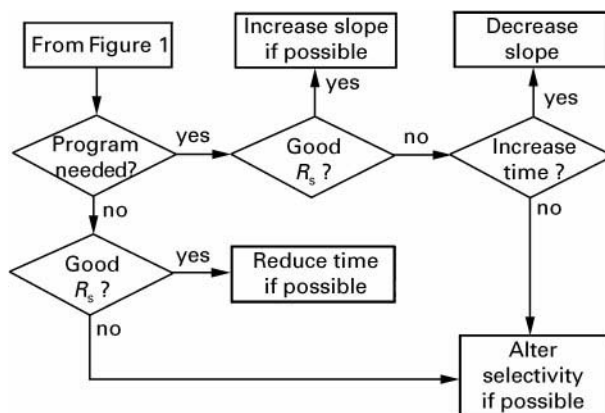

Figure 2 Flow chart for the optimization of an SFC method. R_s denotes resolution (i.e. ratio of distance between two peaks and their average base width).

used, the temperature may be lowered and/or the pressure may be decreased to achieve optimal elution conditions. If a modifier was used then the concentration of modifier may be lowered or the mobile-phase density may be decreased.

When moving the retention of the analytes into the optimum range, it will become apparent whether or not programmed elution is needed. In packed-column SFC this will only be the case if the last analyte has a high retention factor (say $k > 15$) when the first eluting analyte has $k = 1$. In marginal cases, it may be possible to use a different (less selective) stationary phase to avoid programmed analysis. In open-tubular SFC, programmed analysis is often needed just to deal with the excess of solvent introduced with the analytes. Resolution in programmed analysis can typically be increased by lowering the eluent strength (in SFC typically the density) at the start of the program and by lowering the slope (increasing the duration of the gradient segment of the program). In either case, this leads to a longer analysis time. In open-tubular SFC (or when using a fixed restrictor in packed-column SFC) the flow rate may be relatively high, especially in later parts of the program. In this case lowering the flow rate (by preparing a smaller restrictor) may be more rewarding, either by itself, or in combination with lowering the gradient slope.

If a separation under non-programmed conditions leads to abundant resolution between the relevant analytes, it may be possible to decrease the retention time. In order of decreasing rewards, this may be achieved by decreasing the column length, increasing the flow rate, or increasing the eluent strength (increasing the density or the modifier concentration). In the more important case in which the achieved resolution is inadequate, the pressure and/or temperature may be altered, but this often affects retention much more than selectivity (i.e. the retention factors of the various analytes tend to be affected in the same way). If modifiers are being used, different modifiers may lead to different selectivities. However, the most likely road to success is to attempt different stationary phases at this stage.

When we considered the use of different stationary phases at the end of the method-development stage, this was thought not to be very promising. However, in the present situation, at the method-optimization stage, it has already been demonstrated that SFC is a feasible technique for eluting the analytes, but not yet for separating them. Trying different stationary phases with greatly different selectivities may be a rewarding option at this stage.

The actions outlined here may also be relevant when the separation deteriorates at some stage during the development or application of an SFC method.

When this is the case, proper functioning of the equipment should first be verified. The mobile-phase density (pressure and temperature), flow rate and composition may all be verified. If variation in either of these parameters is excluded, then a change in the stationary-phase surface is a probable diagnosis. The column may be simply replaced at this stage, but a few other options are open. These are listed below.

- It is possible that the column is contaminated with very 'heavy' (high molecular weight) or very polar material from the sample or the solvent, that cannot be eluted under SFC conditions. In this case it may be possible to wash the column with a liquid solvent such as 2-propanol, to recondition it in the SFC instrument (without the FID connected), and to use it again for the application.
- It is possible that the column is 'irreversibly' altered by the presence of sample or solvent components. Water on a silica column is the most obvious example. Water may be removed by drying a column overnight at a high temperature (e.g. 250°C) under a small flow of an inert gas (N₂, H₂ or He). A GC oven is very useful for this purpose.
- In case non-programmed conditions are used, it may be advantageous to program the column to different conditions at the end of each analysis, each series of samples, or each working day to avoid column contamination.
- Some columns may change gradually in a truly irreversible manner. The use of amino-derivatized columns is not recommended in combination with CO₂, due to the anticipated formation of carbamates. If such a column is to be used, a gradual change of the stationary phase may necessitate gradual adaptation of the mobile-phase density or composition to maintain adequate resolution. Less dramatic changes of the surface may occur with different stationary phases (e.g. a gradual loss of some chemically bonded ligands from the surface) and these may also be counteracted by small changes in the conditions, rather than by frequently replacing the column.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN THIN-LAYER (PLANAR) CHROMATOGRAPHY

S. Nyiredy, Research Institute for Medicinal Plants, Budakalász, Hungary

Copyright © 2000 Academic Press

Introduction

One of the most critical steps of qualitative and quantitative planar (thin-layer) chromatographic (TLC) analysis is development of a method resulting in sufficient separation. The main steps of method development are summarized in **Figure 1**. The first stage is selection of the stationary phase, the vapour phase, and suitable solvents. This stage is the *sine qua non* of method development, and the selection of these can occasionally immediately result in a suitable separation. For most real separation problems the second stage, optimization of the mobile phase is also necessary. The third part of method development is selection of the final conditions, for example the mode of development, transfer of the mobile phase to an appropriate forced-flow method, and last but not least, the selection of suitable operating parameters. This paper gives essential guides to method development in planar chromatography and draws attention to the most important considerations.

Stationary Phase Selection

TLC separations can be performed on modified, unmodified, and impregnated stationary phases, because of differences between the chemical properties of the sorbent material and those of compounds present in the sample to be separated. Different types of chromatographic process (normal-phase, reversed-phase, partition, and ion exchange chromatography) can be distinguished on the basis of the types of interactions involved. Although more than 90% of TLC separations are performed on silica, chemically bonded phases have recently become increasingly popular for solving special separation problems.

In normal-phase chromatography the hydroxyl groups on the surface of the silica are the polar, active centres which result in the interactions leading to the retention of the compounds to be separated. These interactions are mainly hydrogen-bonding and induced dipole–dipole interactions. The stationary phase can generally be characterized in terms of its specific surface area, specific pore volume, and mean pore diameter.

Unmodified stationary phases include silicas, aluminas, kieselguhr, silicates, controlled-porosity glass, cellulose, starch, gypsum, polyamides, and

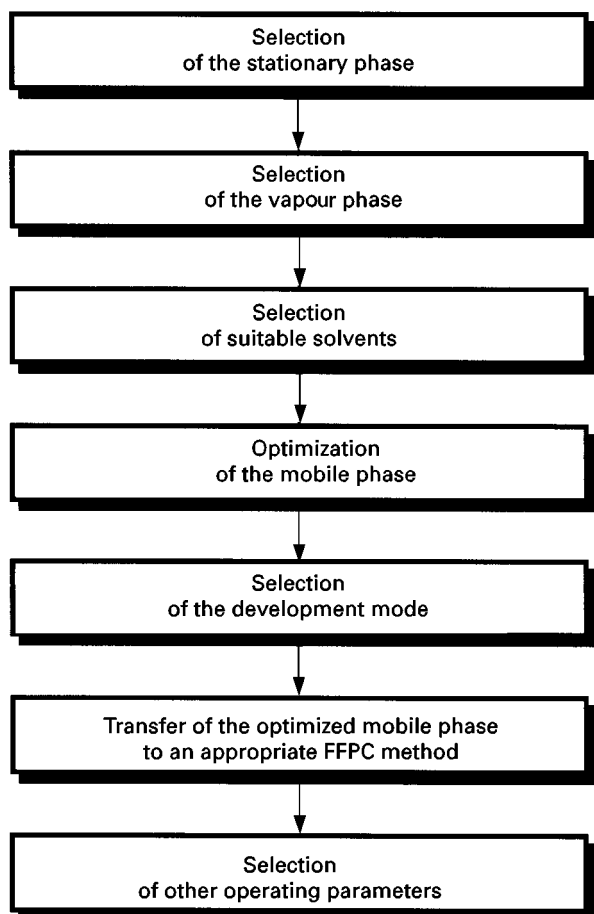

Figure 1 Schematic diagram of method development.

chitin. For TLC separations silica is manufactured by spontaneous polymerization and dehydration of aqueous silicic acid, which is prepared by adding acid to a solution of sodium silicate. The product of this process is an amorphous, porous solid, the specific surface area of which can vary over a wide range (200 to more than $100 \text{ m}^2 \text{ g}^{-1}$, as can the average pore diameter (10–1500 Å).

Modified silicas can be nonpolar or polar adsorbents. The former include silicas bearing alkane or alkene chains or phenyl groups, whereas the polar modified silicas contain cyano, diol, amino, or thiol groups or substance-specific complexing ligands. The structures of some chemically modified silicas are shown in Figure 2.

Almost all the stationary phases used in normal- and reversed-phase column liquid chromatography are also available for TLC. The dimensions of commercially available analytical thin-layer plates are 10×10 , 10×20 or 20×20 cm; the layer thickness is 20 or 25 μm . It is generally accepted that better resolution is obtained on thinner layers (10 μm), depending on the mode of detection. The silica materials commonly used for precoated plates have an average particle size of ca. 11 μm , the size range is from 3 to 18 μm ; for analytical layers prepared in the user's laboratory the average particle size is 15 μm and the range of particle sizes is much greater. The average particle size of precoated high-performance TLC (HPTLC) plates is now 5–6 μm and the range of particle sizes is very small.

	R	Name of stationary phase
	-OH	Silica
	-C ₈ H ₁₇	C ₈ or octyl
	-C ₁₂ H ₂₅	C ₁₂ or dodecyl
	-C ₁₈ H ₃₇	C ₁₈ or octadecyl
	-C ₃ H ₆ -CN	Cyanopropyl
	-C ₃ H ₆ -NH ₂	Aminopropyl
	-C ₃ H ₆ -O-CH ₂ -CHOH-CH ₂ OH	Diol
	-C ₄ H ₈ -chiral layer	Chiral

Figure 2 The structures of some commercially available surface-modified silicas.

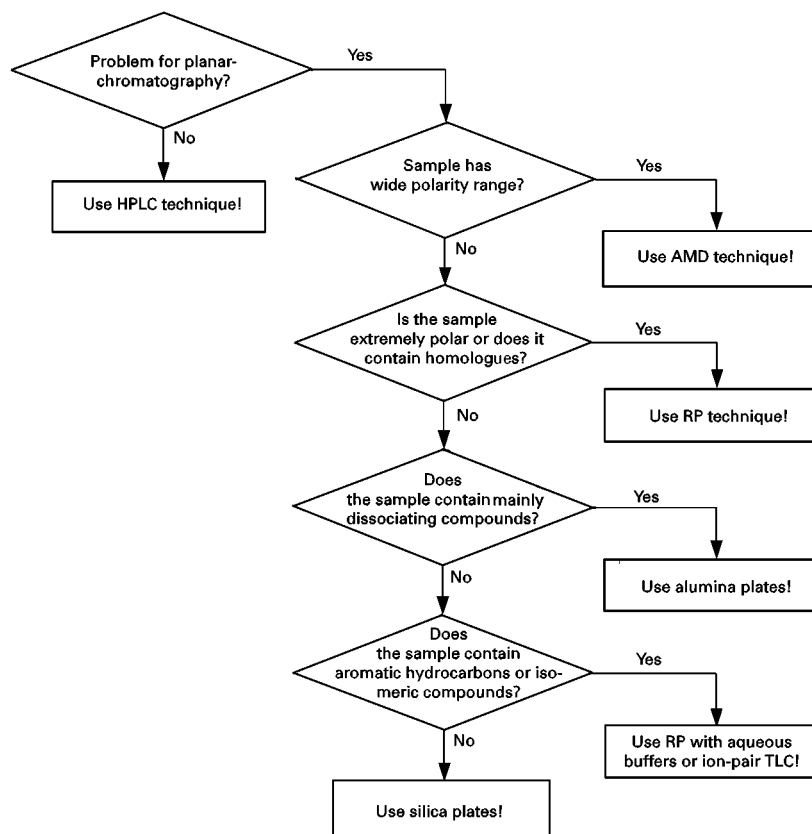

Figure 3 Flow chart illustrating a systematic approach for the selection of the appropriate separation technique and stationary phase.

Precoated analytical layers with a preadsorbent zone are also commercially available for linear development. This zone serves to hold the sample until development begins. Compounds soluble in the solvent system pass through the preadsorbent zone and are concentrated in a narrow band on entering the chromatographic layer; this improves resolution. **Figure 3** gives a decision flow chart for the systematic selection of the appropriate separation technique and stationary phase.

Vapour Phase Selection

In planar chromatography the separation process occurs in a three-phase system of stationary, mobile, and vapour phases, all of which interact both with each other and with the operating conditions. Selection of chamber type and vapour space is a variable offered only by planar chromatography as the third dimension of the chromatographic parameters. The role of the vapour phase in TLC is well known, although little attention is given to this in practice.

In planar chromatography two basic types of chromatographic chamber must be distinguished. In the common normal (N) chamber the distance

between the layer and the wall of the chromatographic tank is more than 3 mm. If this distance is smaller, the chamber is said to have the S configuration. Both types of chamber can be used for unsaturated or saturated systems. As a rule of thumb, if the sample contains fewer than seven compounds to be quantitatively determined, saturated N chambers must be selected for method development. If the sample contains more than seven substances, or the separation is very difficult, S chambers must be selected which enable transfer of the optimized mobile phase by forced-flow.

Often the separation problem cannot be solved by use of conventional TLC with solvent migration by capillary action, because of the relatively modest separating power of the method. In such circumstances use of one of the different forced-flow techniques is necessary; this must be considered during selection of the vapour phase. The chambers used for forced-flow planar separations can be also assigned to the above two categories. The chambers used for overpressured layer chromatography (OPLC) are unsaturated S chambers, theoretically and practically devoid of any vapour space. This must be considered in the selection of appropriate solvents and during the

Figure 4 The saturation grade of different forced-flow methods, in comparison with the N and S chambers.

optimization of the solvent system. In rotation planar chromatography (RPC) the size, and thus the extent of saturation, of the vapour phase can be varied. In RPC the micro and ultramicro chambers belong to the S-chamber type. Because in microchamber RPC the plate rotates with the small chromatographic chamber, and the distance between the layer and the lid of the chamber is less than 2 mm, the vapour space is rapidly saturated. In ultramicrochamber RPC the lid of the chamber is placed directly on the plate and so in practice there is no vapour space, as in OPLC.

When a mobile phase is transferred from a chromatographic tank separation to a forced-flow technique, the vapour phase can be characterized on the basis of the saturation grade (S_G). The S_G value of

a given chromatographic chamber can be calculated by dividing the sum of the hR_F values of the three furthest-migrating substances by the sum of the hR_F values of all the components, subtracting the result from 1, and multiplying the answer by 100. The saturation grade can be used as a measure of the reproducibility of separations with given stationary and mobile phases and at different temperatures and humidity; this enables transfer of the mobile phase to other vapour-phase conditions. **Figure 4** shows the saturation grade of the different chromatographic chambers. The lines indicate suggested mobile phase transfer possibilities; the dotted line indicates other mobile phases which might be used, but with less probability of success.

Figure 5 Flow chart illustrating a systematic approach for the selection of the appropriate chromatographic chamber and vapour phase.

Among the forced-flow methods the highest separating power is obtained with OPLC, because of the optimum mobile phase velocity on the HPTLC plate and the greater separation distance. If, therefore, the quality of the final separation is likely to be determined by the separation distance, OPLC and, for the preassay, the unsaturated S chamber must be selected. If RPC equipment is available for improving the efficiency of the final separation, the choice of chromatographic tank for the preassay depends on the types of compound to be separated. If the acidic or basic character of the vapour phase is important for the separation, a saturated S-chamber (micro-chamber) should be used; if this is not available, a saturated N chamber is the right selection for the TLC pre-assay. If the mobile phase is to be transferred

to a U-RPC separation, an unsaturated S chamber (ultramicro chamber) must be chosen. These considerations are summarized in Figure 5.

Selection of Suitable Solvents

The modern strategy of solvent selection is based on the solvent classification by Snyder, who classified more than 80 solvents into eight groups for normal-phase chromatography according to their properties as proton acceptors (x_a) and proton donors (x_d), and their dipole-dipole interactions (x_n).

For, selection of suitable solvents, preliminary experiments are performed on silica TLC plates with the nine solvents indicated by stars in Table 1, which lists the solvents commonly used in planar chromatography.

Table 1 Solvent classification based on solvent strength and selectivity values

Group	Solvent	Solvent strength (S_i)	X_e	X_d	$S_v = \frac{X_e}{X_d}$

*Approximate value.

After these initial TLC experiments with the neat solvents, the solvent strength (S_i) must either be reduced or increased so that the substance zones are distributed between R_F 20 and 80. The two theoretical situations are depicted in Figure 6 (A and P in Figure 6). If the compounds to be separated migrate in the upper third of the plate (A-a in Figure 6) the solvent strength must be reduced by dilution with hexane. If the neat solvents do not cause migration of

the substances, the solvent strength must be increased (P-a in Figure 6) by the addition of water. In both circumstances the solvent strength should be varied so that better distribution of the substance zones is obtained. Consequently, the structures and properties of the compounds to be separated do not have to be known. Their classification as apolar (A) or polar (P) compounds can be made in accordance with their behaviour in these TLC experiments.

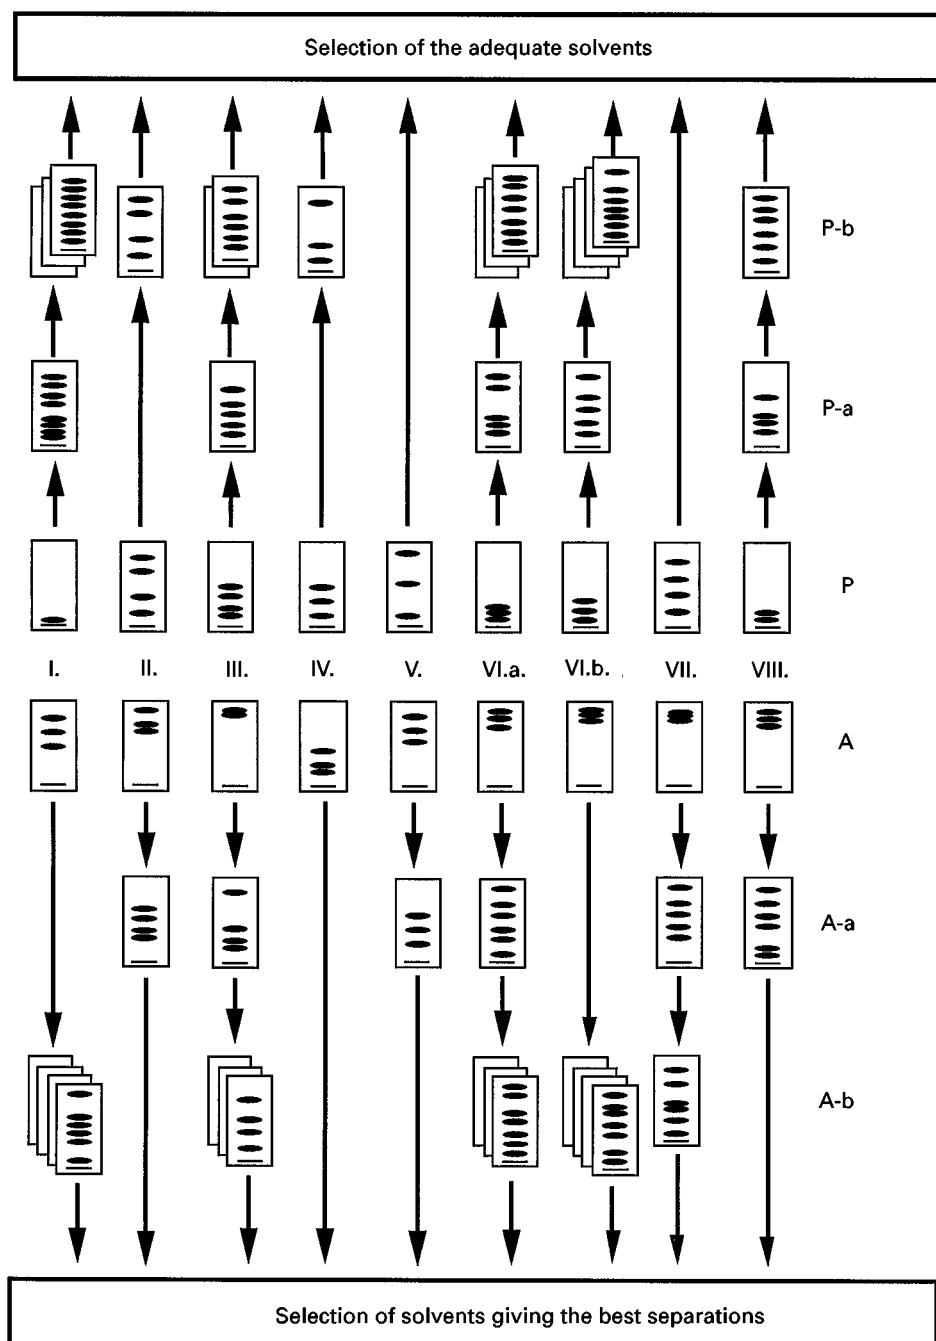

Figure 6 Strategy for the selection of a suitable TLC solvent.

If solvents result in good separation, their homologues or other solvents of the same group can also be tested, as indicated by A-b and P-b in Figure 6. After these experiments the solvents giving the best separations are chosen for further optimization of the separation of apolar compounds. For optimization of the mobile phase for separation of polar compounds, suitable solvents are again selected; the solvent mixture should contain one solvent in which the compounds do not migrate; this is necessary for the transfer of the mobile phase to certain forced-flow techniques. In certain circumstances a suitable separation can be achieved with this solvent-selection strategy. The individual steps of this method of solvent selection are depicted in a flow chart in Figure 7.

Thus the structures and properties of the compounds to be separated do not have to be known for these experiments. After these experiments, the solvents giving adequate separations are chosen for optimization of the mobile phase.

Mobile Phase Optimization

Mobile phase optimization is based both on modification of published data, on experience with the analytes, and on intuition. As sample composition becomes more complex, however, systematic solvent optimization becomes increasingly important. For systematic mobile phase optimization four methods are generally used in planar chromatography:

- window diagram
- sequential simplex method
- Geiss's structural approach
- the 'PRISMA' model.

Because only the 'PRISMA' model is currently suitable for both manual and automatic mobile phase optimization, this method is summarized below.

After the selection of suitable solvents the construction of the actual 'PRISMA' model is begun. In general between two and five solvents might be selected for the construction of the model; modifiers might

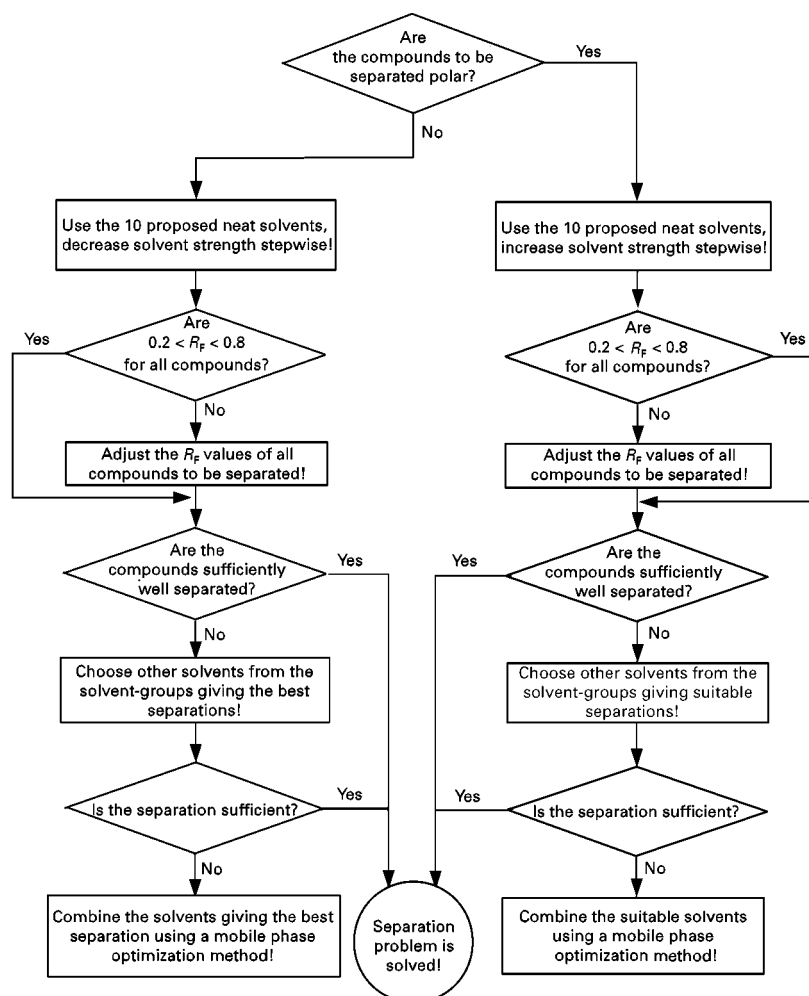

Figure 7 Flow chart illustrating a systematic approach for the selection of suitable solvents.

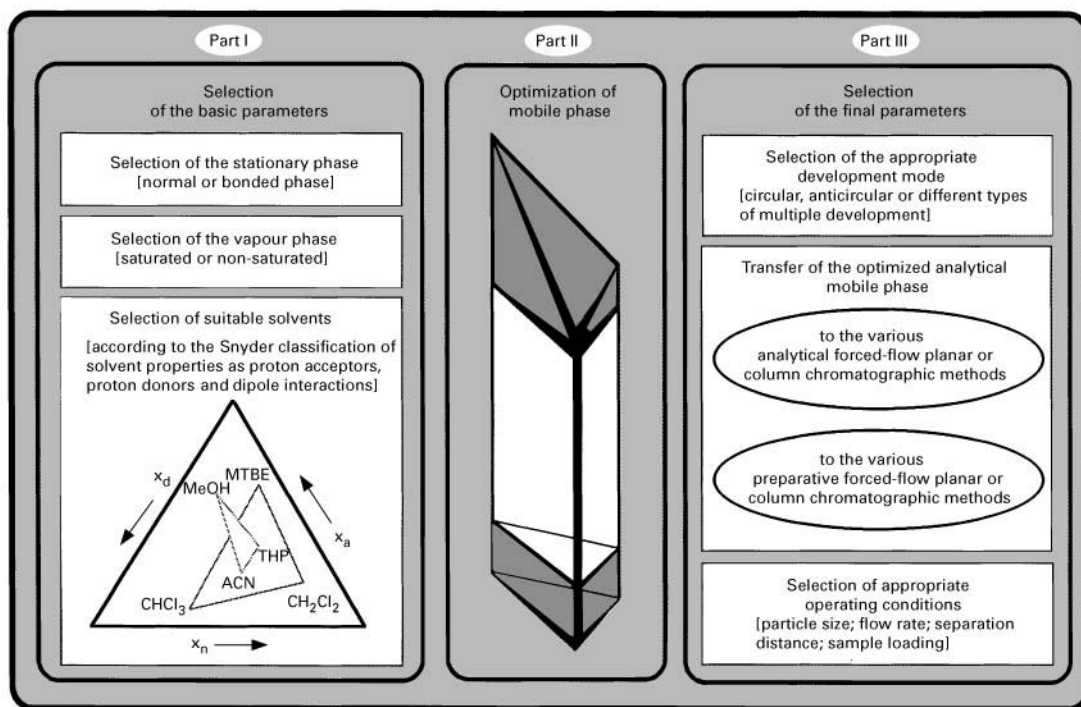

Figure 8 The 'PRISMA' system for the systematic optimization of a planar chromatographic method.

also be added. The actual 'PRISMA' model is a three dimensional geometrical design which correlates the solvent strength with the selectivity value of the mobile phase. The tripartite model (see the central part of **Figure 8**) consists of an irregular top part (light grey), a regular middle part (white) and the lower part (dark grey) symbolizing the modifier(s). When working with silica as the stationary phase, the upper frustum is generally used for the optimization of mobile phases, with or without modifier, for the separation of polar compounds. The regular centre portion of the prism is used for the optimization of mobile phases, with or without modifier, for the separation of apolar compounds. The construction of the model, the role of solvent strength, and the characterization of the selectivity points (P_s) are described extensively in the literature.

The selectivity points on the vertical planes of the regular part of the prism can be obtained by diluting the solvent mixtures with a solvent-strength regulator. Solvent-strength (S_T) values decrease from top to bottom; at the base of the prism S_T is zero. If sections are taken across the regular prism parallel to the base, triangles of different S_T levels are obtained. Obviously, the solvent strength is identical at all points on one of these triangles, and all points on a vertical straight line correspond to the same selectivity point.

For normal-phase chromatography hexane ($S_i = 0$) is the regulator. If reversed-phase plates must be used

for the separation, the regular part of the model is used for the separation, irrespective of the polarity of the compounds to be separated. In these circumstances water, rather than hexane, must be used as the solvent-strength regulator.

The solvent-strength values of the modifier(s) are treated by the 'PRISMA' model as additive terms. For the sake of simplicity, the solvent-strength values of the modifiers are neglected, because they are usually present at low, constant concentrations (generally between 0.1 and 3%, e.g. acids, ion pairs).

Manual Optimization Procedure

The four basic selectivity points within the regular part of the prism ($P_s = 333, 811, 181, 118$) for four solvent mixtures and the three basic selectivity points on the side of the prism ($P_s = 550, 75-25, 25-75$) for three solvent mixtures are emphasized in **Figure 9**. The black points symbolize mixtures of one solvent and the solvent strength regulator (binary systems); the dark grey points symbolize mixtures of two solvents and the regulator (ternary systems); and the three-digit numbers symbolize mixtures of three solvents and the regulator (quaternary systems).

If three solvents were selected for the separation of apolar compounds, optimization is performed within the regular part of the model with the help of the four basic selectivity points. The steps for optimizing the solvent combination for apolar compounds are

Figure 9 Favoured selectivity points for mobile phase optimization.

depicted in a flow chart in **Figure 10**. If two solvents were selected, the optimization is performed along the side of the prism. In both circumstances the solvent strength is adjusted and then different selectivity points are tested. If three to five solvents are selected as best, the number of solvents is reduced on the basis of criteria such as the number of compounds separated and the ΔR_F values obtained. If the solvent combinations tested with this strategy do not result in a sufficient separation, or at least the beginnings of a separation, of important pairs of substances, other solvents must be selected and the process must be repeated, as indicated in the flow chart.

For the separation of apolar compounds the optimization is generally a rapid process because a few experiments are sufficient to evaluate the optimum mobile-phase composition.

For polar compounds, the optimization is always started on the top irregular triangle of the model, either within the triangle, when three solvents were selected, or along one side, when two solvents were selected. Water is usually used as a modifier to increase solvent strength and reduce tailing; if water is used, several selectivity points cannot be tested because of immiscibility problems (especially near $P_s = 811$).

Changing the selectivity points on the top triangle also changes the solvent strength; thus a small change in the selectivity point might result in a large difference in resolution, especially when the solvent

strength of the selected solvents differs substantially. The subsequent procedure is similar to that for the apolar compounds, but the solvent strength must be adjusted after a suitable selectivity is found. The flow chart for the optimization of the solvent combination for polar compounds is shown in **Figure 11**.

In contrast to the separation of apolar compounds, optimization is a longer process for polar substances because of the simultaneous change in solvent strength and selectivity. When water, in particular, is one of the solvents selected for the construction of the triangle, a small change in selectivity results in extreme changes in resolution. More chromatographic experience is, therefore, necessary if the separation problem is to be solved rapidly.

Manual optimization of the mobile phase must be performed until at least the beginnings of a separation of the compounds is obtained. This can usually be achieved with the first 'PRISMA' combination, assuming the individual solvents were selected correctly.

Automatic Optimization Procedure

The basis of automatic mobile-phase optimization, the correlation between mobile-phase composition and resolution for saturated TLC systems, can be described by mathematical functions. The correlation between bR_F values and the selectivity points at a constant solvent strength level can be expressed by

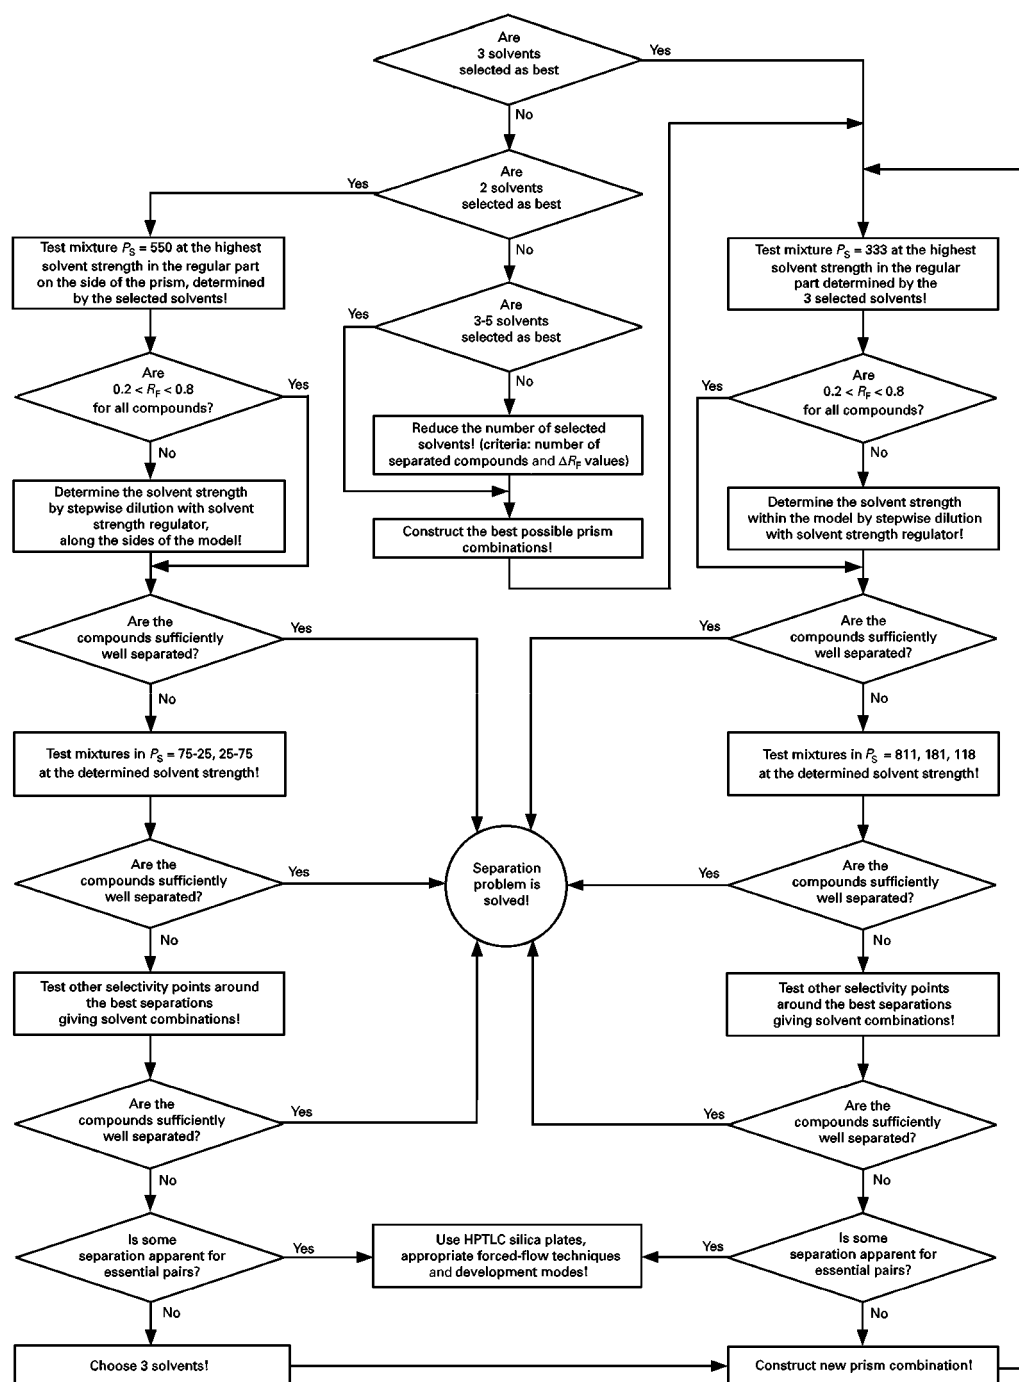

Figure 10 Flow chart illustrating a systematic approach for the optimization of the mobile phase for the separation of nonplanar compounds.

the function:

$$bR_F = a(P_S)^2 + b(P_S) + c$$

For quaternary solvent systems, the correlation between bR_F values and solvent strength at a constant selectivity point can be expressed by the function:

$$\ln bR_F = d(S_T) + e$$

Because the vertical correlation can be linearized, measurements on three solvent-strength levels are needed to calculate the bR_F values for all selectivity points in the spatial design. These correlations are also relevant when modifiers are used in constant amounts, for different classes of substance. From these correlations of bR_F values with the selectivity of the mobile phase, the chromatographic behaviour of

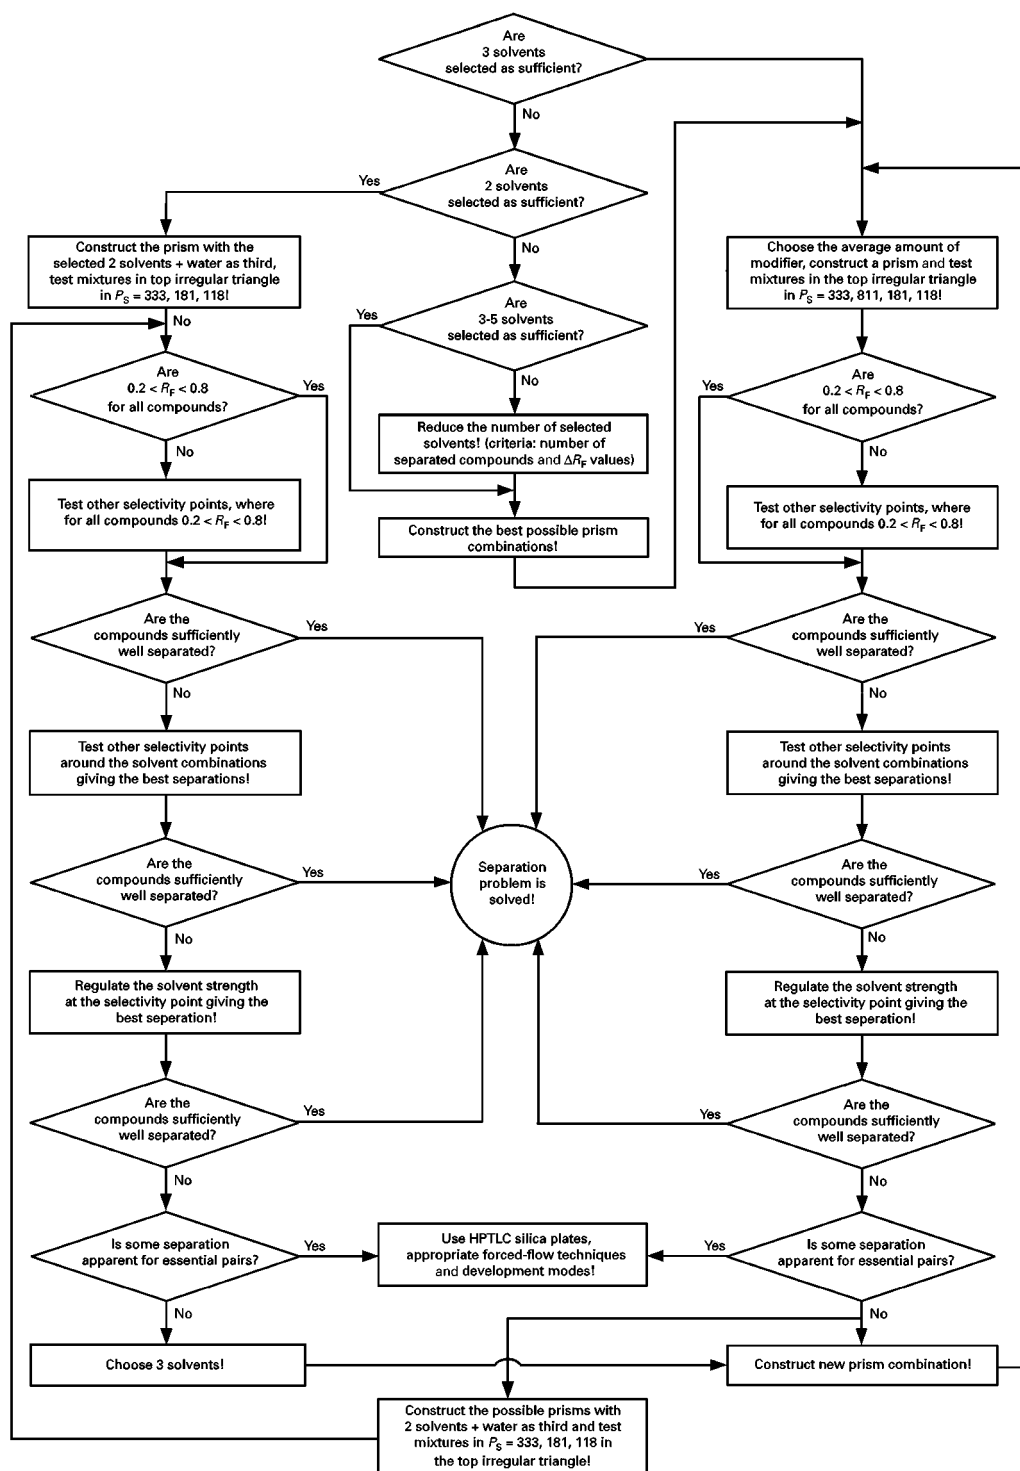

Figure 11 Flow chart illustrating a systematic approach for the optimization of the mobile phase for the separation of polar compounds.

substances to be separated can be predicted for all selectivity values in saturated chromatographic chambers.

The separation quality of predicted chromatograms can be assessed by use of a chromatographic

response function (CRF). The optimum composition can be found by a simple mathematical procedure which maximizes the CRF by monitoring its dependence upon mobile-phase composition. Twelve measurements are necessary to discover a local opti-

Table 2 Required measurements for automatic mobile phase optimization to achieve the global optimum

Solvent strength	Selectivity points					
S_{T1}	811	631	118	343	136	181

num, and fifteen for the global optimum. To increase the accuracy, six measurements at three different solvent strength levels (18 experiments) are necessary, as is seen in Table 2.

Selection of the Mode of Development

Planar chromatography differs from all other chromatographic methods in that it enables selection of the optimum mode of development; the linear mode of development is used most frequently. Because ascending development has no theoretical advantage over horizontal development, the latter, being more adaptable, has become increasingly common in recent years.

The advantage of circular development, where the solvent system migrates radially from the centre of the plate to the periphery, is well known for the separation of compounds in the lower R_F range. Working with the same mobile phase, the resolution is about 4–5 times higher in circular than in linear development mode, as is seen in Figure 12. This statement is only valid if the samples are spotted exactly at the centre ($x = 0$ cm). If the distance between the sample and the mobile phase inlet is, e.g. 2 cm, there is no significant difference in the lower R_F range between circular and linear development (see Figure 12). Development can, however, be started at a point displaced from the centre if a filter-paper ring is used to achieve higher mobile-phase velocity. Under these conditions many samples can be applied and the advantages of circular development can be exploited.

**Figure 12** Effect on the ΔR_F value of the distance between mobile phase inlet and sample.

In anticircular development the mobile phase is applied to the layer as a circle and flows towards the centre. Because the solvent flow velocity decreases with the square of the distance, but the area wetted also decreases with the square of the distance travelled, the speed of mobile-phase migration is practically constant. Although anticircular development is rarely used, it is an accepted approach in TLC if resolution must be increased in the higher R_F range.

The multiple development (MD) techniques, UMD (unidimensional MD) and IMD (incremental MD) can also be used to increase separating power in the lower R_F range. UMD is the repeated development of the plate over the same development distance with mobile phase of the same composition; between development steps the mobile phase is removed from the layer by careful drying and the dried plate is returned to the development chamber for development under the same chromatographic conditions as previously. IMD is an alternative version of this technique in which successive chromatographic developments are performed over increasing development distances with mobile phase of the same composition. In the IMD first development distance is the shortest and subsequent development steps are over longer distances; the development distance usually increases by equal increments. The last migration distance, the longest, corresponds to the useful development length of the plate (but can depend on the mobile phase employed).

The advantages of the different modes of development can be summarized as follows:

- circular development increases resolution in the lower R_F range
- anticircular development increases resolution in the higher R_F range
- UMD is most effective at improving separation in the lower R_F range
- IMD improves zone-centre separation.

A comparison of these modes of development is presented in Figure 13.

Mobile Phase Transfer

There are two reasons for transferring the optimized TLC mobile phase. The first is that the separation is not sufficiently good and better resolution might be achieved by use of forced-flow methods. The optimized TLC mobile phase is, therefore, transferred without alteration to the U-RPC or OPLC technique. When the latter is used, a prerun must be performed. For separation of nonpolar compounds the prerun can be performed with hexane; for separation of polar

Figure 13 Effect of linear, circular, UMD, and IMD development modes on R_F values in the lower R_F range.

substances the prerun can be performed with any component of the mobile phase in which the components do not migrate. The selection of this solvent

might be considered during optimization of the mobile phase. Highly effective separation can be achieved by use of HPTLC plates and forced-flow techniques.

The second reason for transferring an optimized TLC mobile phase is when scaling up to the various preparative chromatographic systems. As a result of the characterization of the different saturation grade of chromatographic chambers (see **Figure 4**), excellent mobile phase transfer between analytical and preparative planar chromatographic methods and analytical HPLC can be achieved. The transfer can be performed on the basis of the chromatographic conditions used. Dry-filled preparative columns (for flash, low-pressure liquid, and medium-pressure liquid chromatography) can be equilibrated with the solvent used for the prerun in analytical OPLC, whereas if the column is filled by the slurry technique, the slurry must be prepared from the same solvent as was used for the OPLC prerun. In both of these, air bubbles can be eliminated by passage of an appropriate amount of the solvent used for the prerun; preparative separation can then be started with the optimized unsaturated TLC mobile phase.

The possibilities of mobile-phase transfer between the different solid-liquid chromatographic methods are comprehensively summarized in **Figure 14**, which demonstrates the possibilities of direct transfer. Different lines show those applicable to the different methods; dotted lines and thin lines are indicative of offline and online methods, respectively, whereas thick lines indicate the possibility of transfer of the optimized mobile phase without change between different solid-liquid planar and column chromatographic techniques, both offline and online.

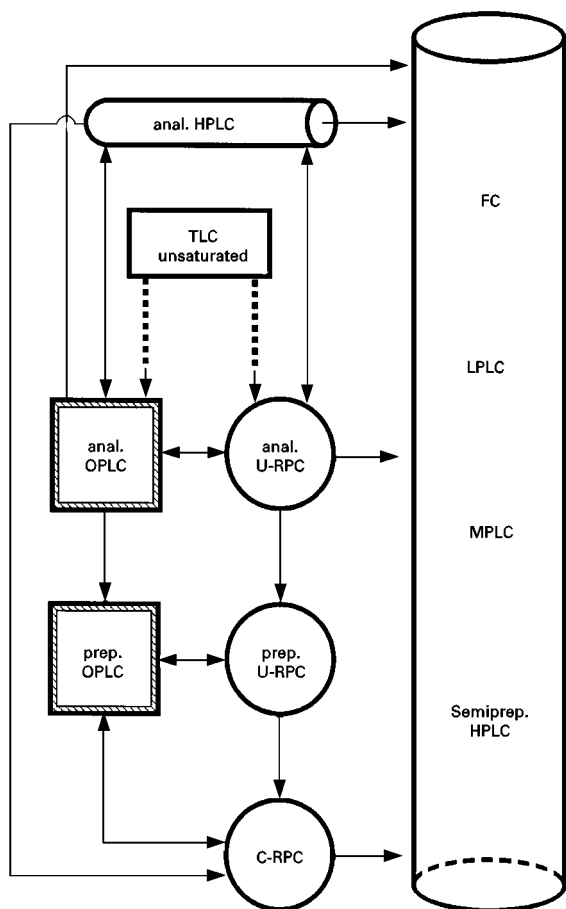

Figure 14 Possibilities of transferring the optimized TLC mobile phase to the different forced-flow planar chromatographic methods, and to preparative column liquid chromatographic techniques.

the migration of the mobile phase. The local mobile-phase velocity can be influenced by the mode of development selected.

In TLC separation efficiency improves with the square root of the separation distance. The optimum, however, depends on the quality of the plate (average particle size and size distribution of the stationary phase), the vapour space, the mode of development, and the properties of the compounds to be separated. The first of these cannot be influenced by the user of precoated plates. The maximum length of commercially available precoated plates is 20 cm. Thus, the maximum separation distance in linear development is 18 cm. The efficiency and rapidity of planar chromatography can be increased by the use of a novel category of multilayer OPLC, long-distance OPLC, by use of which the separation efficiency is increased significantly. In this technique the end of the first plate has a slit-like perforation through which the mobile phase is transferred to a second layer. Clearly, on this basis, a very long separation distance can be achieved by combining one plate with another.

Sample application is one of the most important stages of successful planar chromatography. The amount of applied sample depends on the determination method. Generally, μg and ng quantities of sample can be determined, but even less than 100 pmol substance per chromatogram zone has been reported.

During method development, the separation distance always depends on the mode of development and the forced-flow technique used, and on the development distance; this is summarized in **Figure 15** in the form of a flow-chart.

In normal circumstances alteration of temperature is not an effective means of modifying selectivity and maximizing resolution. If two compounds are unresolved at a given temperature, they normally remain unseparated at other temperatures, irrespective of whether N- or S-chambers are used. It can generally be stated that in saturated chromatographic chambers, which are most commonly used, the temperature does not have a great influence on separations. A change of $\pm 5^\circ\text{C}$ results in a change in hR_F of less than 3. Nevertheless, in the interest of reproducibility in duplicate separations it is important to note the working temperature. Remarkably, temperature is now being found to play an important role in the selectivity and efficiency of OPLC separations.

Strategy of Method Development

The 'PRISMA' optimization system is a strategy for method development in liquid chromatography. Fig-

ure 8, which shows the 'PRISMA' system for planar chromatography, consists of three parts. The first part is the selection of the basic parameters; stationary and vapour phases and suitable solvents, the last according to the Snyder classification. The second part is the optimization of the mobile phase, using the 'PRISMA' optimization model. The third part is the selection of the final parameters; the mode of development, transfer of the mobile phase to the appropriate forced-flow method and, last but not least, the selection of suitable operating conditions. The 'PRISMA' system enables the combination of the appropriate mode of development with the appropriate forced-flow technique by the use of a mobile phase of optimized composition; this offers special possibilities for solving difficult separation problems. This system provides guidelines for method development in planar chromatography.

ESSENTIAL GUIDES TO METHOD DEVELOPMENT IN TWO-DIMENSIONAL ELECTROPHORESIS

M. J. Dunn, Imperial College School of Medicine,
Harefield Hospital, Middlesex, UK

Copyright © 2000 Academic Press

Introduction

Most one-dimensional (1-D) methods of polyacrylamide gel electrophoresis are limited to the resolution of 100 or so protein zones. These techniques are therefore not suitable for the analysis of complex mixtures containing several thousands of proteins, such as total protein homogenates of whole cells and tissue. In addition, they are only able to separate proteins on the basis of a single physico-chemical property. For example, the observation of a particular zone following SDS-PAGE does not imply protein heterogeneity, but simply indicates that any proteins present in that zone have nearly identical size properties, while their charge (and other) properties could be very different.

The best approach to this problem is to combine two different 1-D methods into a 2-D procedure. Ideally, the methods used for each dimension should be selected by their ability to separate proteins according to different properties in each dimension. Thus, if each method when used alone is able to resolve 100 protein zones, it would be expected that up to 10 000 proteins might be resolved when these methods are used orthogonally. This level of resolution has rarely been achieved in practice, but nevertheless 2-D has become the method of choice for the analysis of patterns of protein expression in whole cells, tissues and organisms; the area now known as proteomics.

History of 2-D

The first protein separation by 2-D is attributed to Smithies and Poulik who in 1956 described a combination of paper and starch gel electrophoresis for the separation of serum proteins. Since that time, subsequent advances in electrophoresis, such as the use of polyacrylamide gels, discontinuous buffer systems, gradient gels, SDS-PAGE, and isoelectric focusing (IEF) have all resulted in the development of improved methods of 2-D. These developments cul-

minated in the 1970s with publications from several independent groups describing a combination of a first-dimension separation by IEF under denaturing conditions with a second dimension separation by SDS-PAGE. This coupling of IEF with SDS-PAGE resulted in a method of 2-D which separates proteins according to two independent parameters, charge and size.

The O'Farrell Method of 2-D

The method described by O'Farrell in 1975 has formed the basis of almost all subsequent developments in 2-D, and several thousand papers have been published using this technique in the 25 years following its publication. This method was optimized for the separation of the proteins of *Escherichia coli* (*E. coli*) and used a combination of IEF in cylindrical gels (cast in glass capillary tubes) containing 8 M urea and 2% w/v of the non-ionic detergent, Nonidet P-40 (NP-40), with the SDS-PAGE system of Laemmli. This method was able to resolve around 500 proteins from *E. coli*. It has subsequently been applied to a wide variety of samples.

Limitations of the O'Farrell Method

The main problem with the 2-D method of O'Farrell is associated with the synthetic carrier ampholytes (SCA) which are used to generate the pH gradient in the IEF dimension. SCA are produced by a complex synthetic process which is difficult to control reproducibly. This results in considerable batch-to-batch variability and limits the reproducibility and consistency of 2-D separations. Perhaps more importantly SCA are relatively small molecules, which are not fixed within the IEF gel. As a consequence, the electroendosmotic flow of water that occurs during IEF results in migration of the SCA molecules towards the cathode.

This process, known as 'cathodic drift', results in pH gradient instability and is exacerbated using tube gels due to the negatively charged groups present on the walls of the glass capillaries. In practice, pH gradients using the O'Farrell method of 2-D rarely extend far beyond pH 7, with the resultant loss of the basic proteins. This problem was recognized by O'Farrell, who developed an alternative procedure,

known as non-equilibrium pH gradient electrophoresis (NEPHGE), for the 2-D separation of basic proteins. In this method, separation occurs on the basis of protein mobility in the presence of a rapidly forming pH gradient, but reproducibility is extremely difficult to control. Fortunately, this problem was solved with the development of immobilized pH gradient (IPG) IEF.

2-D Using IPG IEF

IPG IEF gels are prepared using Immoblines (Amersham Pharmacia Biotech), a series of eight acrylamide derivatives with the structure $\text{CH}_2=\text{CH}-\text{CO}-\text{NH}-\text{R}$, where R contains either a carboxyl or tertiary amino group. These form a series of buffers with different pK values distributed through-

Figure 1 Schematic diagram of the procedure of 2-D using IPG IEF. (Courtesy of A. Görg, Technical University, Munich, Germany).

out the pH range 3 to 10. The appropriate IPG reagents, calculated according to published recipes, are added to the mixture used for gel polymerization. Thus, during polymerization, the buffering groups which will form the pH gradient are covalently attached via vinyl bonds to the polyacrylamide backbone. IPG generated in this way are, therefore, immune to the effects of electroendosmosis, so that they provide the opportunity to carry out IEF separations which are extremely stable, allowing the true equilibrium state to be attained.

Initial attempts to implement the IPG technology to 2-D separations encountered several problems. Fortunately, largely due to the work of Görg and her colleagues, these problems have been solved and IPG IEF has become the method of choice for the first dimension separation of 2-D. The method is shown schematically in **Figure 1**. Briefly, IPG slab gels of the desired pH range are cast (**Figure 1(B)**) according to the extensive library of published recipes. After polymerization, the gels are washed, dried and stored at -20°C . The required number of gel strips (3–5 mm wide) for 2-D are cut off of the slab using a paper cutter (**Figure 1(C)**). Alternatively, a range of ready-made strips is available commercially from Amersham Pharmacia Biotech. IPG strips of any desired

length can be used, but it should be remembered that, in general, the larger the separation area of a 2-D gel, the more proteins can be resolved. Strips of 18 cm are usually employed for high-resolution separations, while shorter strips (7 or 11 cm) are used for rapid screening applications.

A choice of a linear pH gradient from 3.5 to 10 is often useful for the initial analysis of a new type of sample. However, for many samples this can result in loss of resolution in the region of pH 4 to 7, in which the pI values of many proteins occur. This problem can be overcome to some extent with the use of a non-linear pH 3.5–pH 10 IPG IEF gel, in which the pH 4–7 region contains a much flatter gradient than in the pH 7–10.5 region. This allows good separation in the pH 4–7 region while still resolving the majority of the more basic species (**Figure 2**). However, use of a pH 4–7 IPG IEF gel will result in even better protein separation (**Figure 3**). Commercial IPG strips are available for these pH ranges (Amersham Pharmacia Biotech). Laboratory-made IPG strips with either very narrow pH gradients (spanning 1 pH or less) can be useful for separating components with very similar pI values, while very basic pH gradients can be used to advantage for certain types of sample, such as ribosomal proteins and nuclear proteins.

Figure 2 A 2-D separation of 100 μg heart proteins using a nonlinear pH 3.5 to 10 IPG IEF gel in the first dimension. The protein pattern was visualized by silver staining. The scale at the top indicates the nonlinear pH gradient obtained using an IPG 3-10 NL strip for the first dimension IEF separation. The scale at the left indicates the size separation in the range 15 to 150 kDa using a 15% SDS-PAGE gel in the second dimension.

Figure 3 A 2-D separation of 100 µg heart proteins using a linear pH 4 to 7 IPG IEF gel in the first dimension. The protein pattern was visualized by silver staining. The scale at the top indicates the linear pH gradient obtained using an IPG 4-7 strip for the first dimension IEF separation. The scale at the left indicates the size separation in the range 10 to 150 kDa using a 10% SDS-PAGE gel in the second dimension.

For use in 2-D, the strips are rehydrated in a re-swelling cassette (**Figure 1(D)**) in a solution containing 8 M urea, 0.5% non-ionic (e.g. NP-40, Triton X-100) or zwitterionic (CHAPS) detergent (3-[(cholamidopropyl)dimethylammonio]-1-propanesulfonate), 15 mM DTT and 0.2% synthetic carrier ampholyte (SCA) of the appropriate pH range. The strips are then placed directly on the surface of the cooling plate of a horizontal flat-bed electrophoresis apparatus (**Figure 1(E)**). A convenient alternative is to use the special strip tray available from Pharmacia (**Figure 1(E)**). This tray is fitted with a corrugated plastic plate which contains grooves allowing easy alignment of the IPG strips. In addition, the tray is fitted with bars carrying the electrodes and a bar fitted with sample cups allowing the application of samples at any desired point on the gel surface. This tray is filled with silicone oil which protects the gel from the effects of the atmosphere during IEF. Horizontal streaking can often be observed at the basic end of 2-D protein profiles, particularly when IPG 6-10 is used for the first dimension. This problem can be resolved by applying an extra electrode strip soaked in 15 mM DTT on the surface of the IPG strip alongside the cathodic electrode strip. This has the advantage

that the DTT within the gel, which migrates towards the anode during IEF, is replenished by the DTT released from the strip at the anode. An alternative approach is to use the non-charged reducing agent, tributyl phosphine (TBP), which does not migrate during IEF and has been found to greatly improve protein solubility during IEF.

Sample Preparation

There is no universal method of sample preparation for 2-D due to the diverse nature of samples which can be analysed. Whatever method is used, it is essential to minimize protein modifications which can result in artefactual spots on 2-D protein patterns. In particular, samples containing urea should not be heated as this will lead to charge heterogeneity as a result of protein carbamylation by isocyanate ions formed from the decomposition of urea. Proteases present within samples can also readily result in artefactual spots, so that samples should be subjected to minimal handling and kept cold at all times. Protease inhibitors can also be added.

Liquid samples containing a relatively high protein concentration (e.g. serum, plasma) require little or no

pre-treatment prior to 2-D. However, less concentrated solutions (e.g. urine, cerebrospinal fluid (CSF), amniotic fluid) often require concentration by methods such as lyophilization, or precipitation with trichloroacetic acid (TCA) or acetone. Solid tissue samples must usually be disrupted in the presence of solubilization solution. For small samples this is readily achieved by crushing the sample in liquid nitrogen using a pestle and mortar, while larger tissue samples must be homogenized using a suitable device. Cell suspensions can be readily harvested by centrifugation, while cells adherent to a substrate, such as a tissue culture flask or dish, should be collected by scraping (the use of proteases should be avoided to prevent possible sample degradation). Alternatively, the cells can be detached by lysis directly in a small volume of sample solubilization solution.

Sample Solubilization

The most popular method for protein solubilization for 2-D is that originally described by O'Farrell, using a mixture of 9.5 M urea, 4% w/v NP-40, 1% w/v DTT and 2% w/v SCA. While this method works well for the majority of samples, it is not universally applicable, with membrane proteins representing a particular challenge. The zwitterionic detergent, CHAPS has been found to be effective for the solubilization of membrane proteins, particularly when used at a concentration of 4% w/v in combination with a mixture of 2 M thiourea and 8 M urea. Linear sulfobetaine detergents, such as SB 3-10 or 3-12, are also effective solubilizing agents, but these are not compatible with high concentrations of urea. This can be overcome by using these reagents at 2% w/v in combination with 5 M urea, 2 M thiourea and 2% CHAPS.

The presence of nucleic acids can be problematic during IEF. This is due to an increase in the viscosity of the sample and in some cases formation of complexes with the sample proteins, leading to artefactual migration and streaking. If problems of this type are suspected, it is best to degrade the nucleic acid by the addition of a suitable pure (i.e. protease free) endonuclease to the sample solubilization solution.

Sample Reduction

Protein disulfide bonds are normally reduced with free thiol-containing reagents such as DTT or β -mercaptoethanol. However, reagents such as DTT are charged so that they migrate out of the gel during IEF, leading to reoxidation of the sample proteins which can result in loss of sample solubility. It has recently been reported that replacing the thiol-containing re-

ducing agents with a non-charged reducing agent such as tributyl phosphine (TBP) can greatly increase protein solubility during the IEF dimension and result in increased transfer to the second dimension gel.

Sample Application and Running Conditions

Samples are usually applied into silicone rubber frames or special sample cups (Figure 1(E)) placed either at the anodic or cathodic end of the IPG strips, the optimum position being determined empirically for each type of sample. The initial voltage should be limited to 150 V for 30 min to allow maximal sample entry and then progressively increased until 3500 V is attained. The time required for the run depends on several factors, including the type of sample, the amount of protein applied, the length of the IPG strips, and the pH gradient. The IEF run should be performed at 20°C, as at lower temperatures there is a risk of urea crystallization and higher temperatures have been found to result in alterations in the relative positions of some proteins on the final 2-D patterns. Some typical running conditions are given in Table 1.

This method of sample application can result in protein precipitation and the effect is more pronounced when high protein loadings (1 mg or more) are used. The problem can be overcome by reswelling the IPG strips directly in the solution containing the protein sample to be analysed. Very high protein loads (>10 mg) have been successfully separated using this method, but there can be a selective loss of high molecular weight, very basic and membrane proteins. Recently a new integrated instrument, named the IPGPhor (Amersham Pharmacia Biotech), has been developed to simplify the IPG IEF dimension 2-D. This instrument features a strip holder that provides for the rehydration of individual IPG strips with or without sample, optional separate sample loading, and subsequent IEF, all without handling the strip after it is placed in the ceramic strip holder. The

Table 1 Suggested running conditions for 18 cm IPG strips for the first, IEF dimension of 2-D. The strips should be run at 0.05 mA per strip (2 mA maximum total), 0.5 W maximum, 20°C

Voltage (maximum)	IPG strip (pH range)	Time
150	All	30 min
300	All	60 min
1500	All	60 min
3500	4-7	42 000 Vh
	4-8	35 000 Vh
	4-9	30 000 Vh
	6-10	35 000 Vh
	3-10.5	25 000 Vh

instrument can accommodate up to 12 individual strip holders and incorporates Peltier solid-state cooling and a programmable 8000 V, 1.5 mA power supply.

Equilibration Between Dimensions

After the IPG IEF dimension, strips can be used immediately for the second dimension. Alternatively, strips can be stored between two sheets of plastic film at -80°C for periods of several months. Prior to the second-dimension separation, it is essential that the IEF gels are equilibrated to allow the separated proteins to interact fully with sodium dodecyl sulfate (SDS) so that they will migrate properly during SDS-PAGE (Figure 1(F)). The recommended protocol is to incubate the IPG IEF gel strips for 15 min in 50 mM Tris buffer, pH 8.8 containing 2% w/v SDS, 1% w/v DTT, 6 M urea and 30% w/v glycerol. The urea and glycerol are used to reduce electroosmotic effects which otherwise result in reduced protein transfer from the first to the second dimension. This is followed by a further 15 min equilibration in the same solution containing 5% w/v iodoacetamide in place of DTT. The latter step is used to alkylate any free DTT, as otherwise this migrates through the second-dimension SDS-PAGE gel, resulting in an artefact known as 'point-streaking' which can be observed after silver staining. An alternative procedure, allowing equilibration to be achieved in a single step, is to replace the DTT in the equilibration buffer with 5 mM TBP, which is uncharged and so does not migrate during SDS-PAGE.

The Second Dimension

After equilibration, the first dimension IEF gels are applied directly to the surface of the second-dimension SDS-PAGE gels. The SDS-PAGE gels can be of any appropriate single or gradient polyacrylamide, and can be used either in a vertical (Figure 1(I)) or horizontal format (Figure 1(G), 1(H)). The use of vertical formats enables multiple gels to be run simultaneously, which improves reproducibility, while the use of horizontal, 0.5 mm thin SDS gels cast on plastic supports improves the ease of handling the gels and gives rapid separations.

Resolution of 2-D

The resolving capacity of 2-D gels is usually considered to be proportional to the total gel area available for the separation. Using 18 cm long IPG IEF gels in combination with 20 cm long second-dimension SDS-PAGE gels, around 2000 proteins can be readily

resolved. Only a few hundred proteins can be separated using mini-gel formats, but these are much quicker to run and can be useful for rapid screening purposes. For maximum resolution of very complex mixtures, very large format gels (>30 cm in each dimension) can be used. These are reported to be able to separate as many as 5000 to 10 000 proteins from whole cell lysates, but this is achieved at the expense of the ease of gel handling and processing.

Reproducibility of 2-D

Until recently reproducibility was a major problem limiting the more widespread application of 2-D. Using the tube gel technique of O'Farrell, it was often difficult to obtain reproducible separations of a particular type of sample even within a single laboratory, while comparison of 2-D separation patterns generated in different laboratories was often considered to be impossible. The use of dedicated equipment for 2-D, such as the ISO-DALT (Amersham Pharmacia Biotech) and the Investigator (ESA Inc) systems, helps in this regard as it allows the simultaneous electrophoresis of large numbers (between 5 and 20) of 2-D gels under reproducibly controlled conditions. More importantly, inter-laboratory studies of various types of sample (heart, barley, yeast) have unequivocally demonstrated that 2-D using IPG IEF results in 2-D protein separations with very high spatial and quantitative reproducibility.

Proteomics

2-D separation has now matured into a technique which is capable of separating reproducibly thousands of proteins present in samples such as cells, tissues and even whole organisms. Recent developments in methods for the microchemical characterization of proteins, particularly techniques for the analysis of proteins and peptides by mass spectrometry, now make it possible to identify and characterize proteins spots directly from 2-D gels. This has made 2-D separation an ideal tool to use in studies designed to determine the nature and function of the large number of structural genes being identified in various genome initiatives. This area has become known as 'proteomics' and is the subject of a separate article.

4. ANALYTICAL CHIRAL SEPARATION METHODS (IUPAC RECOMMENDATIONS 1997)

Prepared for publication by

V. A. Davankov, Russian Academy of Sciences, Moscow, Russia

© 1997 IUPAC

Abstract

In recent years there has been considerable interest in the synthesis and separation of enantiomers of organic compounds especially because of their importance in the biochemistry and pharmaceutical industry. Frequently the methods used for the separations, for monitoring the progress of an asymmetric synthesis or optical purity of the products are chromatographic with either liquids, gases, or supercritical fluids as the mobile phase. More recently capillary electrophoresis has been added as an analytical chiral separation method.

These applications have led to a number of terms and expressions in addition to those commonly used or recently recommended for the chemistry and physical properties of chiral compounds. This Nomenclature provides the descriptions and definitions for additional terms particularly related to analytical separation methods, and to the formation and enantiomeric purity of chiral products

Introduction

Enantiomers are two chemically identical molecular species which differ from each other as non-superposable mirror images. The most simple and vivid model for enantiomeric structures is the two hands, left and right. Enantiomers, in addition to diastereomers and *cis-trans*-isomers, are thus a special case of stereoisomers.

The chirality (handedness) of enantiomeric molecules is caused by the presence of one or more chirality elements (chirality axis, chirality plane, or chirality centre, e.g. asymmetric carbon atom) in their structure. The chirality sense and optical activity of the enantiomers are determined by their absolute configuration, i.e. the spatial arrangement of the atoms in the molecule. In contrast to their conformation, the configuration of enantiomers cannot be changed without a change in the connectivity of constituent atoms. Designation of the configuration of enantiomers should be made in accordance with the Cahn-Ingold-Prelog *R, S*-system. The Δ - Λ designations for enantiomers of octahedral complexes and the *D, L* Fischer-Rosanoff designations for amino acids and sugars are also in use.

Conventional chemical synthesis, in contrast to asymmetric synthesis, deals mostly with the transformations of achiral compounds. If these reactions result in the formation of a chirality element in the molecule, the reaction product appears to be an equivalent mixture of a pair of enantiomers, a racemate, which is optically inactive. Racemates are also formed through racemisation of chiral compounds. Racemates crystallize in the form of a racemic compound or, less frequently, as a conglomerate.

Separation of the enantiomers comprising the racemate, i.e. the resolution of the racemate, is a common problem in stereochemical research as well as in the preparation of biologically active compounds, in particular, drugs. The problem is that in contrast to diastereomers and all the other types of isomeric species,

enantiomers, in an achiral environment, display identical physical and chemical properties. (Energetic inequivalence of enantiomeric species, which can arise from the violation of parity by the weak interactions [1], is negligibly small- of the order of 10^{-14} J mol⁻¹).

One approach to separate enantiomers, sometimes referred to as indirect enantiomeric resolution, involves the coupling of the enantiomers with an auxiliary chiral reagent to convert them into diastereomers. The diastereomers can then be separated by any achiral separation technique.

Nowadays, direct separation methods are commonly used in which the enantiomers are placed in a chiral environment. As a matter of principle, only chiral selectors or chiral irradiation (e.g. a polarized light beam which consists of two chiral circular-polarised components) can distinguish between two enantiomers. Chiral selectors can be an appropriate chiral molecule or a chiral surface (e.g. a chiral seed crystal). Due to the enantioselectivity (a special case of stereoselectivity) of the interaction with the two enantiomers, the chiral selector either transforms the enantiomers at a different rate into new chemical entities (kinetic enantioselectivity) or forms labile molecular adducts of differing stability with the enantiomers (thermodynamic enantioselectivity). Enzymic selective transformation of L-enantiomers of racemic D,L-amino acids is a typical example of a kinetically enantioselective process (kinetic resolution). Enantioselective (chiral) chromatography does not modify the enantiomeric species to be separated and thus represents an example of a thermodynamically enantioselective process.

Direct enantiomeric resolutions are only feasible in chromatographic systems which contain an appropriate chiral selector. The latter can be incorporated into the stationary phase (chiral stationary phase) or be permanently bonded to or coated onto the surface of the column packing material (chiral bonded and chiral coated stationary phases). In all these cases it is appropriate to refer to the chromatographic column as an enantioselective (chiral) column. Enantioselective chromatography can also be performed on achiral chromatographic columns using the required chiral selector as a chiral mobile phase or a chiral mobile phase additive. Combinations of several chiral selectors in the mobile phase [2] as well as mobile and stationary phases [3] are also feasible.

In the case of chiral stationary phases, the enantiomer that forms the more stable association with the chiral selector will be the more strongly retained species of the racemate. The enantioselectivity of the chiral chromatographic system is then expressed as the ratio of the retention factors of the two enantiomers. This ratio may approach the value of the thermodynamic enantioselectivity of the association of the chiral selector with the enantiomers. This situation occurs when the association with the chiral selector governs the retention of the enantiomers in the chromatographic system and other, non-selective types of solute-sorbent interactions are negligible. On other hand, a chiral mobile phase reduces the retention of the solute enantiomer which forms a stronger association with the chiral selector. Here again, the limit for the enantioselectivity of the chiral chromatographic system is set by the enantioselectivity of the selector-solute association (in the mobile phase). However, in the majority of chiral mobile phase systems, the chiral selector as well as its associates with the solute enantiomers are distributed between the mobile and stationary phases. The effective enantioselectivity of the chromatographic system will therefore be proportional to the ratio of the enantioselectivities of the association processes in the stationary and mobile phases [4].

Interaction of the chiral selector of the system with the enantiomers of the solute results in the formation of two labile diastereomers. These differ in their thermodynamic stability, provided that at least three active points of the selector participate in the interaction with corresponding sites of the solute molecule. This three-point interaction rule is generally valid for enantioselective chromatography, with the extension to the rule, stating that one of the required interactions may be mediated by the adsorption of the two components of the interacting pair onto the sorbent surface [5].

Because of the multiplicity and complexity of the interactions of the enantiomers to be separated with the chiral selector, sorbent surface and other components of the chromatographic system, the total enantioselectivity can depend strongly on the composition, pH and temperature of the mobile phase. Therefore, in papers on enantioselective chromatography, it is important to define these parameters.

Enantioselective chromatography and capillary electrophoresis are extensively employed in the analysis of the enantiomeric composition (enantiomeric excess, optical purity) of chiral compounds. Liquid and supercritical fluid chromatography are also used for the isolation of chiral compounds from racemic mixtures on a preparative scale.

Enantioselective separations have been realised in all possible separation techniques, including gas chromatography, column liquid chromatography, thin-layer chromatography, supercritical fluid chromatography, as well as electromigration methods, countercurrent liquid chromatography and liquid-liquid extractions.

Numerous review papers and special monographs [6–15] describe the technical details as well as the achievements and potential of these important modern separation techniques.

In the following glossary of definitions and terms related to the chromatographic and capillary-electrophoretic separation of chiral compounds some terms (those marked with asterisks) were defined in the Basic Terminology of Stereochemistry, recently published by the IUPAC Joint Working Party on Stereochemical Terminology [16]. Some of these definitions contain further cross references which are to be found in the original paper.

Terms and Definitions

General Terms Related to Chirality

***Chirality** The geometric property of a rigid object (or spatial arrangement of points or atoms) of being non-superposable on its mirror image; such an object has no symmetry elements of the second kind (a mirror plane, $\sigma = S_1$, a centre of inversion, $i = S_2$, a rotation-reflection axis, S_{2n}). If the object is superposable on its mirror image the object is described as being achiral. *See also* handedness.

Diastereoisomers (Diastereomers) *see* diastereoisomerism

Diastereoisomerism *Stereoisomerism* other than enantiomerism and *cis-trans* isomerism. Diastereoisomers (or diastereomers) are stereoisomers not related as mirror images. Diastereoisomers are characterised by differences in physical properties, and by differences in chemical behaviour towards achiral as well as chiral reagents.

***Enantiomer** One of a pair of molecular entities which are mirror images of each other and non-superposable. *See also* enantiomorph.

***Stereoisomers** Isomers that possess identical constitution but which differ in the arrangement of their atoms in space. *See* enantiomer, diastereomer, *cis-trans*-isomers.

Terms Related to the Separated Process

Chiral additive The *chiral selector* which has been added as a component of a mobile phase or electrophoretic medium.

Chiral mobile phase A mobile phase containing a *chiral selector*.

Chiral selector The *chiral* component of the separation system capable of interacting *enantioselectively* with the *enantiomers* to be separated.

Chiral stationary phase A stationary phase which incorporates a *chiral selector*. In not a constituent of the stationary phase as a whole, the chiral selector can be chemically bonded to (*chiral bonded stationary phase*) or immobilized onto the surface of a solid support or column wall (*chiral coated stationary phase*), or simply dissolved in the liquid stationary phase.

Enantioselective chromatography (electrophoresis) The separation of *enantiomeric* species due to the *enantioselectivity* of their interaction with the *chiral selector(s)* of a chromatographic (electrophoretic) system. Also called *Chiral chromatography (electrophoresis)*.

Enantioselective column A chromatographic column containing a *chiral stationary phase*. Also called a *chiral column*.

Enantioselectivity (in chiral separations) The preferential interaction with the chiral selector of one enantiomer over the other.

Enantioselectivity of a chromatographic (electrophoretic) system The ratio of the retention factors of two solute enantiomers in a chiral chromatographic (electrophoretic) system.

Terms Related to the Chiral Purity of the Sample

***Diastereoisomer excess/Diastereoisomeric excess** This is defined by analogy with *enantiomer excess*, as $D_1 - D_2$ [and the percent diastereoisomer excess as $100(D_1 - D_2)$], where the mole fractions of the two diastereoisomers in a mixture or the fractional yields of two diastereoisomers formed in a reaction are D_1 and D_2 ($D_1 + D_2 = 1$). The term is not applicable if more than two diastereoisomers are present. Frequently this term is abbreviated to d.e. *See* stereoselectivity; diastereoisomerism.

***Enantiomer excess/Enantiomeric excess** For a mixture of (+) and (-) enantiomers, with composition given as the mole or weight fractions $F_{(+)}$ and $F_{(-)}$ (where $F_{(+)} + F_{(-)} = 1$) the enantiomeric excess is defined as $|F_{(+)} - F_{(-)}|$ (and the percent enantiomer excess by $100|F_{(+)} - F_{(-)}|$). Frequently this term is abbreviated as e.e. *See* optical purity.

***Enantiomeric purity** *see* Enantiomer excess

***Optical purity** The ratio of the observed optical rotation of a sample consisting of a mixture of enantiomers to the optical rotation of one pure enantiomer. *See* enantiomeric excess.

5. BIOLOGICAL BUFFERS

Table 1 This table of frequently used buffers gives the pK_a value at 25°C and the useful pH range of each buffer. The buffers are listed in order of increasing pH

Acronym	Name	Mol. wt.	pK_a	Useful pH range
MES	2-(<i>N</i> -Morpholino)ethanesulphonic acid	195.2	6.1	5.5–6.7
BIS TRIS	<i>Bis</i> (2-hydroxyethyl)iminotris(hydroxymethyl)methane	209.2	6.5	5.8–7.2
ADA	<i>N</i> -(2-Acetamido)-2-iminodiacetic acid	190.2	6.6	6.0–7.2
ACES	2-[(2-Amino-2-oxoethyl)amino]ethanesulphonic acid	182.2	6.8	6.1–7.5
PIPES	Piperazine- <i>N,N'</i> - <i>bis</i> (2-ethanesulphonic acid)	302.4	6.8	6.1–7.5
MOPSO	3-(<i>N</i> -Morpholino)-2-hydroxypropanesulphonic acid	225.3	6.9	6.2–7.6
BIS TRIS PROPANE	1,3- <i>Bis</i> [<i>tris</i> (hydroxymethyl)methylamino]propane	282.3	6.8 ^a	6.3–9.5
BES	<i>N,N</i> - <i>Bis</i> (2-hydroxyethyl)-2-aminoethanesulphonic acid	213.2	7.1	6.4–7.8
MOPS	3-(<i>N</i> -Morpholino)propanesulphonic acid	209.3	7.2	6.5–7.9
HEPES	<i>N</i> -(2-Hydroxyethyl)piperazine- <i>N'</i> -(2-ethanesulphonic acid)	238.3	7.5	6.8–8.2
TES	<i>N</i> - <i>Tris</i> (hydroxymethyl)methyl-2-aminoethanesulphonic acid	229.2	7.5	6.8–8.2
DIPSO	3-[<i>N,N</i> - <i>Bis</i> (2-hydroxyethyl)amino]-2-hydroxypropanesulphonic acid	243.3	7.6	7.0–8.2
TAPSO	3-[<i>N</i> - <i>Tris</i> (hydroxymethyl)methylamino]-2-hydroxypropanesulphonic acid	259.3	7.6	7.0–8.2
TRIZMA	<i>Tris</i> (hydroxymethyl)aminomethane			
HEPPSO	<i>N</i> -(2-hydroxyethyl)piperazine- <i>N'</i> -(2-hydroxypropanesulphonic acid)	121.1	8.1	7.0–9.1
POPSO	Piperazine- <i>N,N'</i> - <i>bis</i> (2-hydroxypropanesulphonic acid)	268.3	7.8	7.1–8.5
EPPS	<i>N</i> -(2-Hydroxyethyl)piperazine- <i>N'</i> -(3-propanesulphonic acid)	362.4	7.8	7.2–8.5
TEA	Triethanolamine	252.3	8.0	7.3–8.7
TRICINE	<i>N</i> - <i>Tris</i> (hydroxymethyl)methylglycine	149.2	7.8	7.3–8.3
BICINE	<i>N,N</i> - <i>Bis</i> (2-hydroxyethyl)glycine	179.2	8.1	7.4–8.8
TAPS	<i>N</i> - <i>Tris</i> (hydroxymethyl)methyl-3-aminopropanesulphonic acid	163.2	8.3	7.6–9.0
AMPSO	3-[(1,1-Dimethyl-2-hydroxyethyl)amino]-2-hydroxypropanesulphonic acid	243.3	8.4	7.7–9.1
		227.3	9.0	8.3–9.7
CHES	2-(<i>N</i> -Cyclohexylamino)ethanesulphonic acid	207.3	9.3	8.6–10.0
CAPSO	3-(Cyclohexylamino)-2-hydroxy-1-propanesulphonic acid	237.3	9.6	8.9–10.3
AMP	2-Amino-2-methyl-1-propanol	89.1	9.7	9.0–10.5
CAPS	3-(Cyclohexylamino)-1-propanesulphonic acid	221.3	10.4	9.7–11.1

^a $pK_a = 9.0$ for the second dissociation stage.

6A. CLASSIFICATION AND CHARACTERIZATION OF STATIONARY PHASES FOR LIQUID CHROMATOGRAPHY (IUPAC RECOMMENDATIONS 1997)

Descriptive Terminology

Prepared for publication by

R. M. Smith, Loughborough University, Loughborough, Leicestershire, UK

A. Marton, University of Veszprém, Veszprém, Hungary

© 1997 IUPAC

Abstract

A wide range of stationary phases and column packing materials have been developed over the years for liquid chromatography and these need to be described accurately and unambiguously. The present paper, which is the first of a series planned for this area, recommends terms for the description of the stationary phase materials and their properties and expands the list of terms given in Nomenclature of Chromatography [PAC, 1993, 65, 819–872.]. It concentrates on the chemical properties and chromatographic role of the materials. Many of the terms to describe their physical properties as particles have been discussed in a recent paper on the characterization of porous solids [PAC, 1994, 66, 1739–1758].

Index

Introduction

General descriptive terms for the stationary phase

Terms for the nature of the stationary phase material

Modes of application of stationary phase materials

Physical properties of the stationary phase materials

References

Appendix. Terms from the Nomenclature for Chromatography [1] which have been redefined

Introduction

One of the major problems throughout analytical liquid (and supercritical fluid) chromatography has been in reproducibly transferring methods between columns and systems. One of the main factors is that there are large differences in the chemical and physical properties of stationary phase materials, even between those which are nominally the same, such as octadecylsilyl (ODS)-bonded silicas. In addition, the methods used to describe the physical and chemical properties of these stationary phase materials are not standardized and even the terms used have not been agreed. In the laboratory, the behaviour of the stationary phases is also dependent on the nature of the interaction of specific mobile phases and analytes with the stationary phase.

The present discussions will concentrate on chromatographic applications of stationary phases. The standardization of analytical stationary phase materials falls into two areas.

- a) Terms needed to describe the physical and chemical properties of the stationary phase materials.
- b) Methods and tests needed to describe the operational properties of these materials. This is an important area but one where research is still active and as yet no consensus of approaches and techniques has been reached. This topic still requires much experimental work and was considered inappropriate for the Commission to consider at this time. It is also the subject of work by ASTM committees and others who are in a better position to carry out experimental work and to organise comparative studies.

The present paper considers the first of these areas and recommends a number of terms for the description of stationary phase materials and their chemical and physical properties. Some descriptive terms for the stationary phase have already been defined in the Nomenclature of Chromatography (NC) [1] and in the recently published Nomenclature for Analytical Chiral Separation methods (CS) [2]. In addition many of the Recommendations for the Characterization of Porous Solids published by the Physical Chemistry Division [3] are relevant to the physical description of stationary phase materials.

Amended and expanded definitions are now recommended for a number of the terms. The original versions are included in the Appendix.

General Descriptive Terms for the Stationary Phase

A number of these terms are generally applicable throughout chromatography and were defined previously in the Nomenclature for Chromatography (NC) [1]. However, in a number of cases, an inappropriate capitalization was used in NC, particularly of the second word in terms and these have been corrected in the definitions reproduced here.

Stationary Phase [Replaces NC 1.1.05]

One of the two phases forming a chromatographic system. It is the part of a chromatographic system responsible for the retention of the analytes, which are being carried through the system by the *mobile phase*. It may be a solid, a gel or a liquid. If a liquid, it may be distributed on a *solid support*. This *solid support* may or may not contribute to the separation process. The liquid may also be chemically bonded to the solid (*bonded phase*) or immobilized onto it (*immobilized phase*).

The expression *chromatographic bed* or *sorbent* may be used as a general term to denote any of the different forms in which the stationary phase is used.

Note: Particularly in gas chromatography where the stationary phase is most often a liquid, the term *liquid phase* is used for it as compared to the *gas phase*, i.e. the mobile phase. However, particularly in the early development of liquid chromatography, the term ‘liquid phase’ had also been used to characterize the mobile phase as compared to the ‘solid phase’ i.e. the stationary phase. Due to this ambiguity the use of the term ‘liquid phase’ is discouraged. If the physical state of the stationary phase is to be expressed, the use of the adjective forms, such as *liquid stationary phase* and *solid stationary phase*, *bonded stationary phase* or *immobilized stationary phase*, are recommended.

Packing Material, Stationary Phase Material [Replaces NC 3.1.07]

The *packing* is the active solid, stationary phase plus solid support or swollen gel which is contained in the chromatographic column. In liquid chromatography the usage of the terms *packing material* and *stationary phase material* are often synonymous. The term *packing material* is preferred as a general term for a loose, usually particulate, material intended for chromatographic use before it is packed into the column. Once it is packed and in contact with the mobile phase, it becomes the *stationary phase* as one of the two chromatographic phases. The *stationary phase* usually consists of a specific *stationary phase material*, which has been packed into a column. Both are typically given the same description.

Solid Support (NC 3.1.03)

A solid that holds the stationary phase but, ideally, does not contribute to the separation process.

Continuous Bed Packing

A column packing, which is a single entity, rather than being composed of individual particles.

Carbon Loading (of the Packing Material)

Mass fraction of the packing material which is carbon. Usually taken as a guide to the extent of alkyl substitution on the surface. Usually reported as percentage carbon determined using elemental analysis.

Terms for the Nature of the Stationary Phase Material**Immobilized Stationary Phase (Material) [Replaces, NC 1.1.05.2]**

A stationary phase which has been immobilized on the support particles, or on the inner wall of the column tubing, e.g. by either a physical attraction (*coated stationary phase*), by chemical bonding (*bonded stationary phase*), or by *in situ* polymerisation (*cross-linked stationary phase*) after coating.

Coated stationary phase (material) A material in which a stationary phase is immobilized by a physical attraction to the surface of the solid support.

Filled stationary phase (material) An immobilized stationary phase (*material*) in which a liquid fills the pores of the solid phase.

Bonded stationary phase (material) [Replaces NC 1.1.05.1] A stationary phase which is covalently bonded to solid support particles or to the inside wall of the column tubing. Sometimes referred to as a *bonded phase (material)*. The bonded stationary phase (*material*) may be *monomeric*, *polymeric* or *polymer-grafted phase (material)* and the *stationary phase (material)* can also receive additional treatment to give a *capped (end-capped) stationary phase (material)*.

Bonded phase See *Bonded stationary phase* [Replaces NC 1.1.05.1]

Monomeric-bonded stationary phase (material) Bonded stationary phase (material) prepared using a reagent, usually monofunctional, which reacts with single sites on the surface of the solid support.

Polymeric-bonded stationary phase (material) Bonded stationary phase (material) prepared using a polyfunctional reagent which can react both with the surface of the solid support and/or with additional reagent molecules.

Polymer-grafted stationary phase (material) Bonded stationary phase (material) in which a pre-formed polymer has been bound to the surface by a chemical bond.

Capped stationary phase (material) (also known as end-capped stationary phase (material)) Bonded stationary phase (material) which has been treated with a second (usually less bulky) reagent, which is intended to react with remaining functional (e.g. silanol) groups which have not been substituted by the original reagent because of steric hindrance.

Alkyl-bonded stationary phase (material) Bonded stationary phase (material) in which the group bound to the surface contains an alkyl chain (usually between C₁ and C₁₈).

Phenyl-bonded stationary phase (material) Bonded stationary phase (material) in which the group bound to the surface contains a phenyl group.

Cyano-bonded stationary phase (material) Bonded stationary phase in which the group bound to the surface contains a cyanoalkyl-($-\text{[CH}_2\text{]}_n\text{-CN}$) group.

Diol-bonded stationary phase (material) Bonded stationary phase in which the group bound to the surface contains a vicinal dihydroxyalkyl ($-\text{[CH}_2\text{]}_n\text{-CHOH-CH}_2\text{OH}$) group.

Amino-bonded stationary phase (material) Bonded stationary phase in which the group bound to the surface contains an aminoalkyl- (usually a $-\text{[CH}_2\text{]}_n\text{-NH}_2$) group.

Internal surface reversed-phase (ISRP) materials Bonded stationary phase in which the external surface of the solid support carries different bonded groups from the internal pores (usually an external hydrophilic layer with a more hydrophobic internal layer). Examples include *restricted-access stationary phase (material)* in which polar macromolecules are excluded from the internal pores.

Cross-linked Stationary Phase (Material) A stationary phase (material) in which the liquid phase coating on a solid support has been polymerized or cross-linked after coating to make it insoluble in the mobile phase.

Polymeric Stationary Phase (Material)

Stationary phase (material) based on particles of a cross-linked organic polymeric material. Typical materials are *polystyrene divinylbenzene copolymers* (PS-DVB) and modified PS-DVB materials.

Liquid-coated Stationary Phase (Material)

A material in which a liquid stationary phase is coated on the surface of the solid support.

Modes of Application of Stationary Phase Materials

Stationary phases are often defined in terms of the mode of chromatography being employed in the separation.

Size Exclusion Chromatographic Phases

These phases are described in *Compendium of macromolecular nomenclature* [4] (term 3.4.6). or in the Nomenclature for Chromatography section 6 [1].

Ion-exchange Stationary Phases

The principle terms have already been defined in NC (section 5) and are included here for comparison.

Cation exchanger (NC 5.302) Ion-exchanger with cations as counter-ions. The term *cation-exchange resin* may be used in the case of solid organic polymers.

Anion exchanger (NC 5.3.03) Ion-exchanger with anions as counter-ions. The term *anion-exchange resin* may be used in the case of solid organic polymers.

Chiral Stationary Phase (CS 2.4 [2])

A stationary phase which incorporates a *chiral selector*. If not constituent of the stationary phase as a whole, the chiral selector can be chemically bonded to (*chiral bonded stationary phase*) or immobilized onto the surface of a solid support or column wall (*chiral coated stationary phase*), or simply dissolved in the liquid stationary phase.

Affinity Stationary Phase (Material)

Bonded stationary phase (material) containing attached (adsorbed or covalently bonded) ligand molecules with a specific biological interaction for a particular molecule or small group of related molecules.

Perfusion Stationary Phase (Material)

Stationary phase in which the mobile phase primarily travels through the pores of the stationary phase.

Physical Properties of the Stationary Phase Material

Recommendations for the characterization of porous solids have recently been published by the Commission on Colloid and Surface Chemistry [3] and many of these are relevant to the characterization of stationary phase materials. In particular the conclusions presented in that paper should be noted, **especially, that in many cases absolute values of the parameters such as pore diameter and surface area cannot be obtained.** The measured value frequently depends on the method of measurement (and this should always be stated) and the selection of a method of characterization starts from the intended use of the material. These comments would also apply to the determination of particle diameter. In addition, the calculation methods for average particle diameters, such as number average or weight average, must be reported.

Previously Defined General Terms

Particle diameter (d_p) (NC 3.1.08) The average diameter of the solid particles.

Pore radius (r_p) (NC 3.1.09) The average radius of the pores within the solid particles.

Appendix 1.

Terms from the 'Nomenclature for Chromatography' [1] which have been Redefined.

1.1.05. Stationary phase

One of the two phases forming a chromatographic system. It may be a solid, a gel or a liquid. If a liquid it may be distributed on a solid. This solid may or may not contribute to the separation process. The liquid may also be chemically bonded to the solid (*bonded phase*) or immobilized onto it (*immobilized phase*).

The expression *chromatographic* bed or sorbent may be used as a general term to denote any of the different forms in which the stationary phase is used.

Note: Particularly in gas chromatography where the stationary phase is most often a liquid, the term *liquid phase* is used for it as compared to the *gas phase*, i.e., the mobile phase. However, particularly in the early development of liquid chromatography, the term ‘liquid phase’ had also been used to characterize the mobile phase as compared to the ‘solid phase’, i.e. the stationary phase. Due to this ambiguity the use of the term ‘liquid phase’ is discouraged. If the physical state of the stationary phase is to be expressed the use of the adjective forms, such as *liquid stationary phase* and *solid stationary phase*, *bonded phase* or *immobilized phase*, are recommended.

1.1.05.1. Bonded phase

A stationary phase which is covalently bonded to the support particles or to the inside wall of the column tubing.

1.1.05.2. Immobilized phase

A stationary phase which immobilized on the support particles, or on the inner wall of the column tubing, e.g. by *in situ* polymerization (cross-linking) after coating.

3.1.07. Packing

The active solid, stationary phase plus solid support or swollen gel contained in a tube.

6B. Characterization of Ion Exchange Chromatographic Stationary Phases

Prepared for publication by

A. Marton, University of Veszprém, Veszprém, Hungary

© 1997 IUPAC

Abstract

In order to characterize ion exchange chromatographic stationary phases the thermodynamic exchange constant and the free energy interaction parameters are recommended. These parameters are calculated from the experimentally available corrected selectivity coefficient *vs.* exchanger phase composition functions. The equations used for the calculations have been obtained by introducing the Friedman equation (developed for the calculation of the excess free energy change) into the thermodynamic derivation. The suggested parameters also make possible the estimation of the value of the selectivity coefficient at an arbitrary exchanger phase composition. The characteristic parameters of the ion exchange resins and the equations in a directly suitable form for the estimation of the selectivity coefficient are calculated and presented for several systems.

Introduction

Parameters for the physical and chemical characterization of chromatographic stationary phases including ion exchangers have already been defined [1]. The purpose of this paper is to introduce sensitive numerical parameters for the comparison of operation ion exchange chromatographic stationary phases based on their selectivity coefficient exhibited in a particular ion exchange equilibria. For two competing counter ions (e.g. A^+ and B^{z+}) the problem arises not only because various selectivity coefficients may be assigned to the various commercially available products, but also because the exact value of the selectivity coefficient

may vary considerably with the degree of conversion of the exchanger phase as the ion exchange reaction (1) proceeds.

Here R represents the (usually monovalent) functional group covalently bond to a solid phase. The so-called corrected selectivity coefficient (K') is an experimentally available parameter defined for the above equilibria as:

$$K' = \frac{\bar{x}_B \cdot a_A^z}{\bar{x}_A^z \cdot a_B} \quad (2)$$

Throughout this article, symbols with overbars refer to the resin phase where the standard and reference states of RA and R_zB are taken to the respective mono-ionic forms of the exchanger in equilibrium with water. Symbols without a bar refer to the solution phase where the Henryan standard and reference states are accepted in accordance with conventional practice [2]. \bar{x} denotes mole or, if $z > 1$, equivalent fraction (in general $\bar{x}_i = z_i \cdot \bar{m}_i / \sum z_i \cdot \bar{m}_i$ and the summation is carried out over all counterion molalities \bar{m}_i), a and the parameter \bar{a} (see below) are the activities in the solution and resin phases respectively. For the ultimate characterization and comparison of the selectivity of the exchange reactions the more exactly defined thermodynamic exchange constant, K^T is recommended [2,3]:

$$K^T = \frac{\bar{a}_B \cdot a_A^z}{\bar{a}_A^z \cdot a_B} \quad (3)$$

An extensive compilation of the K^T data for the various ion exchange equilibria has been made in an earlier report of the IUPAC [4]. Since the ion exchange equilibrium constant is directly related to the distribution coefficient of the ion studied its knowledge in the calculation of the retention volume, or generally in the design of ion exchange separations, is indispensable. Considering however, that in the majority of analytical ion exchange separations practically either one or the other end to the mole fraction scale is utilized ($\bar{x}_A \approx 1$ or $\bar{x}_B \approx 1$), the thermodynamic constant could be quite far from the actual (operational) value of the selectivity coefficient. The suggested characterization method is meant to provide a solution for these seemingly conflicting aspects.

Using the concentrated electrolyte solution model of the ion exchange resins, equations were derived for the composition dependence of the selectivity coefficient (see equations on pages 104 and 105 of reference [5]). From the experimentally available functions $\ln K'$ vs. \bar{x}_B the derived relationships make possible both the calculation of the thermodynamic exchange constant and the so-called free energy interaction parameters which, in turn, could be used to calculate the selectivity coefficient at any value of \bar{x}_B . It was proved that the free energy interaction parameters are related to the selectivity controlling properties of the ion exchanger phase, such as the crosslinking of the polymer matrix, the type of the functional group and the size of the exchanging counter ions [5]. The purpose of the suggested method is to characterize the ion exchangers with these parameters in connection with their actual ion exchange reaction. It may also be considered as an operational characterization which uses both the thermodynamic constant and the above mentioned free energy interaction parameters to estimate the value of the corrected selectivity coefficient at an arbitrary exchanger phase composition.

Theoretical Background

When reaction (1) takes place a mixture of the concentrated electrolytes is always formed. The composition of this mixture (\bar{x}_B) varies as the resin is converted from A^+ and B^{z+} form. According to H.L. Friedman [6] the excess free energy change (ΔG^E) accompanying the formation of a two component electrolyte solution mixture at constant ionic strength I (containing a common cation or anion) can be approximated by the equation:

$$\Delta G^E = R \cdot T \cdot I^2 \cdot x_A \cdot x_B \cdot [g_0 + g_1 \cdot (x_A - x_B)] \quad (4)$$

Here x_A and x_B are the mole fractions of the components (e.g. RA and R_zB) and g_0 and g_1 are the so called free energy interaction parameters independent of the composition. These terms have been introduced by

Table 1 Summary of the equations used for the calculations

$\ln K' = a_0 + a_1 \cdot \bar{x}_B + a_2 \cdot \bar{x}_B^2$ (5)	
$a_2 < 0$	$a_2 > 0$
$\bar{g}_0 = \frac{a_1 + a_2}{2 \cdot z}$ (6)	$\bar{g}_0 = \frac{a_1 + a_2}{2 \cdot z}$ (9)
$\bar{g}_1 = \frac{-a_2}{6 \cdot z}$ (7)	$\bar{g}_1 = \frac{a_2}{6 \cdot z}$ (10)
$\ln K^T = a_0 + z \cdot \bar{g}_0 + z \cdot \bar{g}_1$ (8)	$\ln K^T = a_0 + z \cdot \bar{g}_0 - z \cdot \bar{g}_1$ (11)

Friedman to account for the strength of pair and triplet interactions respectively in a concentrated two component electrolyte solution mixture. The existence of a similar mixture of concentrated electrolyte solutions is supposed to be present in the exchanger phase too. It has been pointed out [5] that by introducing eqn. (4) into the thermodynamic derivation the composition dependence of the selectivity coefficient can be expressed conveniently by these free energy interaction parameters. Equations suggested for the calculation of the characteristic ion exchange parameters (\bar{g}_0 , \bar{g}_1 and $\ln K^T$) were taken from reference [5] and are summarized for our purpose in Table 1.

Although a direct, *a priori*, calculation of the free energy interaction parameters for the concentrated electrolyte solution of the exchanger phase is still not feasible a detailed analysis of several literature data proved that their value is dramatically influenced by the crosslinking of the inert (polymer) matrix, by the type and density of the active group of the resin and by the type of the counter ion [5]. Consequently, these parameters by themselves are characteristic for the ion exchange chromatographic stationary phase *i.e.* a difference in their values for the two compared stationary phases indicate differences in relevant structural parameters governing ion exchange selectivity.

Source of Experimental Data and Examples for the Suggested Ion Exchange Stationary Phase Characterization

An important criteria for the application of the equations shown in Table 1 is that the exchange reaction should be completely reversible, where the exchange capacity is freely accessible to the competing counter ions. The exchange equilibrium should be studied at a constant temperature and ionic strength in the full range of mole fraction scale and the corrected selectivity coefficient, K' defined by eqn. (2) should be calculated at each exchanger phase composition. As an application of the above equations, we can consider the following experimental data obtained by Bonner [7] for the Na^+/H^+ exchange reaction on a strongly acidic Dowex 50 \times 8 resin:

\bar{x}_{Na^+} :	0.12	0.22	0.32	0.42	0.58	0.70	0.75	0.86
$\ln K'$:	0.470	0.438	0.438	0.439	0.451	0.405	0.343	0.270

When eqn. (5) of Table 1 is fitted to the above $\ln K'$ vs. \bar{x}_{Na^+} data pairs then the following coefficients are obtained: $a_0 = 0.400$, $a_1 = 0.398$, $a_2 = -0.624$ (the curve fitting program used for the calculation is given in reference [8]). Since $a_2 < 0$ eqns. (6, 7 and 8) of Table 1 can be used for the calculation of the characteristic parameters of the studied exchange equilibria. The obtained values are: $\bar{g}_0 = -0.113$, $\bar{g}_1 = 0.104$, $\ln K^T = 0.39$.

The function describing the dependence of $\ln K'$ on the exchanger phase composition can therefore be given by the so-called selectivity polynomial:

$$\ln K' = 0.400 + 0.398 \cdot \bar{x}_{\text{Na}^+} - 0.624 \cdot \bar{x}_{\text{Na}^+}^2 \quad (12)$$

If in the actual exchange process the estimated value of the stationary phase loading is e.g. 0.1 (or at the other extreme end of the mole fraction scale is e.g. 0.9) then the calculated $\ln K'$ value is 0.433 (or 0.253)

which are certainly more realistic values for the design of an ion exchange separation process than the value of $\ln K^T$ (0.39).

If the experimentally obtained ($\ln K'$ vs. \bar{x}_B) function is concave i.e. $a_2 > 0$ then eqns. (9, 10 and 11) of Table 1 should be used for the calculation of the above parameters. It may also happen that the experimental data fits well with a straight line. In this case the above equations are also valid but, of course, now $a_2 = 0$. The choice between the linear or the quadratic fitting procedures can be made by the comparison of the goodness of fit parameters. It is, in fact, automatically calculated by the referred curve fitting program and the improvement in the goodness of fit can be seen immediately when the degree of the polynomial is changed (e.g. from one to two).

In order to illustrate the wide scope of applicability of the suggested characterization method Tables 2 and 3 show the calculated values of the above discussed equilibrium parameters for a set of systems. The equilibria

selected, mostly from the 'classics' of the ion exchange literature are meant to represent both inorganic and organic cation and anion exchange reactions, where the crosslinking of the polymer matrix, the size of the active group and the size of the counter ion varies considerably.

Conclusion

The nonideal behaviour of the exchanger phase is recognized to be highly characteristic for the ion exchanger as a chromatographic stationary phase. As a quantitative measure of this nonideality the free energy interaction parameters are calculated from the data of equilibrium measurements. These data are then applied to construct the so-called selectivity polynomial which, in turn, can be used to estimate the selectivity coefficient at any required composition of the exchanger phase. Beyond the highly specific, numerically sensitive feature of these parameters their recommendation for the characterization of ion exchange chromatographic stationary phases is further supported by their connection with thermodynamic equilibrium constant of the exchange reaction.

7. CONVERSION OF UNITS

The table below gives conversion factors from a variety of units to the corresponding SI unit. For each physical quantity the name is given, followed by the recommended symbol(s). Then the SI unit is given, followed by the esu, emu, Gaussian unit (Gau), atomic unit (au), and other units in common use, with their conversion factors to SI. The constant ζ which occurs in some of the electromagnetic conversion factors is the (exact) pure number $2.997\,924\,58 \times 10^{10} = c_0/(\text{cms}^{-1})$.

The inclusion of non-SI units in this table should not be taken to imply that their use is to be encouraged. With some exceptions, SI units are always to be preferred to non-SI units. However, since many of the units below are to be found in the scientific literature, it is convenient to tabulate their relation to the SI.

For convenience units in the esu and Gaussian systems are quoted in terms of the four dimensions *length*, *mass*, *time*, and *electric charge*, by including the franklin (Fr) as an abbreviation for the electrostatic unit of charge and $4\pi\epsilon_0$ as a constant with dimensions $(\text{charge})^2/(\text{energy} \times \text{length})$. This gives each physical quantity the same dimensions in all systems, so that all conversion factors are pure numbers. The factors $4\pi\epsilon_0$ and the Fr may be eliminated by writing $\text{Fr} = \text{esu of charge} = \text{erg}^{1/2}\text{cm}^{1/2} = \text{cm}^{3/2}\text{g}^{1/2}\text{s}^{-1}$, $4\pi\epsilon_0 = \epsilon_0^{(\text{ir})} = 1 \text{ Fr}^2 \text{ erg}^{-1} \text{ cm}^{-1} = 1$, to recover esu expressions in terms of three base units. The symbol Fr should be regarded as a compact representation of (esu of charge).

Conversion factors are either given exactly (when the = sign is used), or they are given to the approximation that the corresponding physical constants are known (when the \approx sign is used). In the latter case the uncertainty is always less than ± 5 in the last digit quoted.

<i>Magnetic susceptibility, χ, κ</i>		
SI unit	1	
emu, Gau	1	
(But note: in practice susceptibilities quoted in the context of emu or Gaussian units are always values for $\chi^{(\text{ir})} = \chi/4\pi$; thus when $\chi^{(\text{ir})} = 10^{-6}$, $\chi = 4\pi \times 10^6$)		
<i>Molar magnetic susceptibility, χ^{m}</i>		
SI unit	$\text{m}^3 \text{ mol}^{-1}$	
emu, Gau	$\text{cm}^3 \text{ mol}^{-1}$	$= 10^{-6} \text{ cm}^3 \text{ mol}^{-1}$
(But note: in practice the units $\text{cm}^3 \text{ mol}^{-1}$ usually imply that the irrational molar susceptibility is being quoted, $\chi_{\text{m}}^{(\text{ir})} = \chi_{\text{m}}/4\pi$; for example if $\chi_{\text{m}}^{(\text{ir})} = -15 \times 10^{-6} \text{ cm}^3 \text{ mol}^{-1}$, which is often written as ‘ -15 cgs ppm ’, then $\chi_{\text{m}} = -1.88 \times 10^{-10} \text{ m}^3 \text{ mol}^{-1}$.)		

^aNote that the day is not exactly defined in terms of the second since so-called leap-seconds are added or subtracted from the day semiannually in order to keep the annual average occurrence of midnight at 24:00 on the clock.

^bThe year is not commensurable with the date and not a constant. Prior to 1967, when the atomic standard was introduced, the tropical year 1900 served as the basis for the definition of the second. For the epoch 1900.0, it amounted to $365.242\,198\,79 \text{ d} \approx 31\,556\,925.975 \text{ s}$ and it decreases by 0.530 seconds per century. The calendar years are exactly defined in terms of the day:

Julian year = 365.25 d

Gregorian year = 365.2425 d.

The definition in the table corresponds to the Gregorian year. This is an average based on a year of length 365 days, with leap years of 366 days; leap years are taken *either* when the year is divisible by 4 but is not divisible by 100, *or* when the year is divisible by 400.

^c1 N is approximately the force exerted by the earth upon an apple.

^d $T/^{\circ}\text{R} = (9/5)T/\text{K}$. Also, Celsius temperature θ is related to thermodynamic temperature T by the equation:

$$\theta/^{\circ}\text{C} = T/\text{K} - 273.15$$

Similarly Fahrenheit temperature θ_{F} is related to Celsius temperature θ by the equation:

$$\theta_{\text{F}}/^{\circ}\text{F} = (9/5)(\theta/^{\circ}\text{C}) + 32$$

^eThe name ‘amagat’ is unfortunately used as a unit for both molar volume and amount density. Its value is slightly different for different gases, reflecting the deviation from ideal behaviour for the gas being considered.

^fThe unit röntgen, employed to express exposure to X or γ radiations, is equal to: $\text{R} = 2.58 \times 10^{-4} \text{ C kg}^{-1}$.

^gThe units in quotation marks for electric potential through polarizability may be found in the literature, although they are strictly incorrect; they should be replaced in each case by the units given in the symbol column. Thus, for example, when a quadrupole moment is quoted in ‘ cm^2 ’, the correct unit is $e \text{ cm}^2$; and when a polarizability is quoted in ‘ \AA^3 ’, the correct unit is $4\pi\epsilon_0 \text{\AA}^3$.

^hThe Bohr magneton μ_{B} is sometimes denoted BM (or B.M.), but this is not recommended.

8. DEFINITIONS AND SYMBOLS FOR UNITS

The International System of Units (SI)

The International System of units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built from seven *SI base units*, one for each of the seven dimensionally independent base quantities: they are the metre, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes*, may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units.

Definitions of the SI Base Units

Metre: The metre is the length of path travelled by light in vacuum during a time interval of $1/299\,792\,458$ of a second (17th CGPM, 1983).

Kilogram: The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Second: The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium-133 atom (13th CGPM, 1967).

Ampere: The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 metre apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per metre of length (9th CGPM, 1948).

Kelvin: The kelvin, unit of thermodynamic temperature, is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

Mole: The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles (14th CGPM, 1971).

Examples of the use of the mole

1 mol of H_2 contains about 6.022×10^{23} H_2 molecules, or 12.044×10^{23} H atoms

1 mol of HgCl has a mass of 236.04 g

1 mol of Hg_2Cl_2 has a mass of 472.08 g

1 mol of Hg_2^{2+} has a mass of 401.18 g and a charge of 192.97 kC

1 mol of $\text{Fe}_{0.91}\text{S}$ has a mass of 82.88 g

1 mol of e^- has a mass of 548.60 μm and a charge of -96.49 kC

1 mol of photons whose frequency is 5×10^{14} Hz has energy of about 199.5 kJ

Candela: The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of $(1/683)$ watt per steradian (16th CGPM, 1979).

Names and Symbols for the SI Base Units

The symbols listed here are internationally agreed and should not be changed in other languages or scripts.

Physical quantity	Name of SI unit	Symbol for SI unit
Length	metre	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

SI Derived Units with Special Names and Symbols

Physical quantity	Name of SI unit	Symbol for SI unit	Expression in terms of SI base units
Frequency ^a	hertz	Hz	s^{-1}
Force	newton	N	$m\ kg\ s^{-2}$
Pressure, stress	pascal	Pa	$N\ m^{-2} = m^{-1}\ kg\ s^{-2}$
Energy, work, heat	joule	J	$N\ m = m^2\ kg\ s^{-2}$
Power, radiant flux	watt	W	$J\ s^{-1} = m^2\ kg\ s^{-3}$
Electric charge	coulomb	C	As
Electric potential, electromotive force	volt	V	$J\ C^{-1} = m^2\ kg\ s^{-3}\ A^{-1}$
Electric resistance	ohm	Ω	$V\ A^{-1} = m^2\ kg\ s^{-3}\ A^{-2}$
Electric conductance	siemens	S	$\Omega^{-1} = m^{-2}\ kg^{-1}\ s^3\ A^2$
Electric capacitance	farad	F	$C\ V^{-1} = m^{-2}\ kg^{-1}\ s^4\ A^2$
Magnetic flux density	tesla	T	$V\ s\ m^{-2} = kg\ s^{-2}\ A^{-1}$
Magnetic flux	weber	Wb	$V\ s = m^2\ kg\ s^{-2}\ A^{-1}$
Inductance	henry	H	$V\ A^{-1}\ s = m^2\ kg\ s^{-2}\ A^{-2}$
Celsius temperature ^b	degree Celsius	$^{\circ}C$	K
Luminous flux	lumen	lm	cd sr
Illuminance	lux	lx	cd sr m^{-2}
Activity ^c (radioactive)	becquerel	Bq	s^{-1}
Absorbed dose ^c (of radiation)	gray	Gy	$J\ kg^{-1} = m^2\ s^{-2}$
Dose equivalent ^c (dose equivalent index)	sievert	Sv	$J\ kg^{-1} = m^2\ s^{-2}$
Plane angle ^d	radian	rad	1 $= m\ m^{-1}$
Solid angle ^d	steradian	sr	1 $= m^2\ m^{-2}$

^aFor radial (angular) frequency and for angular velocity the unit $rad\ s^{-1}$, or simply s^{-1} , should be used, and this may *not* be simplified to Hz. The unit Hz should be used *only* for frequency in the sense of cycles per second.

^bThe Celsius temperature θ is defined by the equation $\theta/^{\circ}C = T/K - 273.15$.

The SI unit of Celsius temperature is the degree Celsius, $^{\circ}C$, which is equal to the kelvin, K. $^{\circ}C$ should be treated as a single symbol, with no space between the $^{\circ}$ sign and the letter C. (The symbol $^{\circ}K$, and the symbol $^{\circ}$, should no longer be used).

^cThe units becquerel, gray and sievert are admitted for reasons of safeguarding human health.

^dThe units radian and steradian are described as 'SI supplementary units'. However, in chemistry, as well as in physics, they are usually treated as dimensionless derived units, and this was recognized by CIPM in 1980. Since they are then of dimension 1, this leaves open the possibility of including them or omitting them in expressions of SI derived units. In practice this means that rad and sr may be used when appropriate and may be omitted if clarity is not lost thereby.

SI Derived Units for Other Quantities

This table gives examples of other SI derived units; the list is merely illustrative.

Physical quantity	Expression in terms of SI base units	
Area	m^2	
volume	m^3	
Speed, velocity	m s^{-1}	
Angular velocity	s^{-1} , rad s^{-1}	
Acceleration	m s^{-2}	
Moment of force	N m	$= \text{m}^2 \text{kg s}^{-2}$
Wavenumber	m^{-1}	
Density, mass density	kg m^{-3}	
Specific volume	$\text{m}^3 \text{kg}^{-1}$	
Amount concentraion ^a	mol m^{-3}	
Molar volume	$\text{m}^3 \text{mol}^{-1}$	
Heat capacity, entropy	J K^{-1}	$= \text{m}^2 \text{kg s}^{-2} \text{K}^{-1}$
Molar heat capacity, molar entropy	$\text{J K}^{-1} \text{mol}^{-1}$	$= \text{m}^2 \text{kg s}^{-2} \text{K}^{-1} \text{mol}^{-1}$
Specific heat capacity, specific entropy	$\text{J K}^{-1} \text{kg}^{-1}$	$= \text{m}^2 \text{s}^{-2} \text{K}^{-1}$
Molar energy	J mol^{-1}	$= \text{m}^2 \text{kg s}^{-2} \text{mol}^{-1}$
Specific energy	J Kg^{-1}	$= \text{m}^2 \text{s}^{-2}$
Energy density	J m^{-3}	$= \text{m}^{-1} \text{kg s}^{-2}$
Surface tension	$\text{N m}^{-1} = \text{J m}^{-2}$	$= \text{kg s}^{-2}$
Heat flux density, irradiance	W m^{-2}	$= \text{kg s}^{-3}$
Thermal conductivity	$\text{W m}^{-1} \text{K}^{-1}$	$= \text{m kg s}^{-3} \text{K}^{-1}$
Kinematic viscosity, diffusion coefficient	$\text{m}^2 \text{s}^{-1}$	
Dynamic viscosity	$\text{N s m}^{-2} = \text{Pa s}$	$= \text{m}^{-1} \text{kg s}^{-1}$
Electric charge density	C m^{-3}	$= \text{m}^{-3} \text{s A}$
Electric current density	A m^{-2}	
Conductivity	S m^{-1}	$= \text{m}^{-3} \text{kg}^{-1} \text{s}^3 \text{A}^2$
Molar conductivity	$\text{S m}^2 \text{mol}^{-1}$	$= \text{kg}^{-1} \text{mol}^{-1} \text{s}^3 \text{A}^2$
Permittivity	F m^{-1}	$= \text{m}^{-3} \text{kg}^{-1} \text{s}^{-4} \text{A}^2$
Permeability	H m^{-1}	$= \text{m kg s}^{-2} \text{A}^{-2}$
Electric field strength	V m^{-1}	$= \text{m kg s}^{-3} \text{A}^{-1}$
Magnetic field strength	A m^{-1}	
Luminance	cd m^{-2}	
Exposure (X and γ rays)	C kg^{-1}	$= \text{kg}^{-1} \text{s A}$
Absorbed dose rate	Gy s^{-1}	$= \text{m}^2 \text{s}^{-3}$

^aThe words ‘amount concentration’ are an abbreviation for ‘amount-of-substance concentration’. When there is not likely to be any ambiguity this quantity may be called simply ‘concentration’.

SI Prefixes

To signify decimal multiples and submultiples of SI units the following prefixes may be used.

Submultiple	Prefix	Symbol	Multiple	Prefix	Symbol
10^{-1}	deci	d	10	deca	da
10^{-2}	centi	c	10^2	hecto	h
10^{-3}	milli	m	10^3	kilo	k
10^{-6}	micro	μ	10^6	mega	M
10^{-9}	nano	n	10^9	giga	G
10^{-12}	pico	p	10^{12}	tera	T

Submultiple	Prefix	Symbol	Multiple	Prefix	Symbol
10^{-15}	femto	f	10^{15}	peta	P
10^{-18}	atto	a	10^{18}	exa	E
10^{-21}	zepto	z	10^{21}	zetta	Z
10^{-24}	yocto	y	10^{24}	yotta	Y

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

Prefix symbols should be printed in roman (upright) type with no space between the prefix and the unit symbol.

Example kilometre, km

When a prefix is used with a unit symbol, the combination is taken as a new symbol that can be raised to any power without the use of parentheses.

Examples $1 \text{ cm}^3 = (0.01 \text{ m})^3 = 10^{-6} \text{ m}^3$
 $1 \mu\text{s}^{-1} = (10^{-6} \text{ s})^{-1} = 10^{-6} \text{ s}^{-1}$
 $1 \text{ V/cm} = 100 \text{ V/m}$
 $1 \text{ mmol/dm}^3 = 1 \text{ mol m}^{-3}$

A prefix should never be used on its own, and prefixes are not to be combined into compound prefixes.

Example pm, not $\mu\mu\text{m}$

The names and symbols of decimal multiples and submultiples of the SI base unit of mass, the kg, which already contains a prefix, are constructed by adding the appropriate prefix to the word gram and symbol g.

Examples mg, not μkg ; Mg, not kkg

The SI prefixes are not to be used with $^{\circ}\text{C}$.

ISO has recommended standard representations of the prefix symbols for use with limited character sets.

Units in Use Together with the SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as millilitre, ml; millibar, mbar; megaelectronvolt, MeV; kilotonne, kt. A more extensive list of non-SI units, with conversion factors to the corresponding SI units, is given in the appendix, Conversion of Units.

Physical quantity	Name of unit	Symbol for unit	Value in SI units
Time	minute	min	60 s
Time	hour	h	3600 s
Time	day	d	86 400 s
Plane angle	degree	$^{\circ}$	$(\pi/180) \text{ rad}$
Plane angle	minute	'	$(\pi/10\,800) \text{ rad}$
Plane angle	second	"	$(\pi/648\,000) \text{ rad}$
Length	ångström ^a	Å	10^{-10} m
Area	barn	b	10^{-28} m^2
Volume	litre	l, L	$\text{dm}^3 = 10^{-3} \text{ m}^3$
Mass	tonne	t	$\text{Mg} = 10^3 \text{ kg}$
Pressure	bar ^a	bar	$10^5 \text{ Pa} = 10^5 \text{ N m}^{-2}$
Energy	electronvolt ^b	eV(= $e \times \text{V}$)	$\approx 1.60218 \times 10^{-19} \text{ J}$
Mass	unified atomic mass unit ^{b,c}	u(= $m_a(^{12}\text{C})/12$)	$\approx 1.66054 \times 10^{-27} \text{ kg}$

^aThe ångström and the bar are approved by CIPM for 'temporary use with SI units', until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

^bThe values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants e (for the electronvolt) and N_A (for the unified atomic mass unit), which are determined by experiment. See appendix, Fundamental Constants.

^cThe unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

Atomic Units

For the purposes of quantum mechanical calculations of electronic wavefunctions, it is convenient to regard certain fundamental constants (and combinations of such constants) as though they were units. They are customarily called *atomic units* (abbreviated: au), and they may be regarded as forming a coherent system of units for the calculation of electronic properties in theoretical chemistry, although there is no authority from CGPM for treating them as units. The first five atomic units in the table below have special names and symbols. Only four of these are independent; all others may be derived by multiplication and division in the usual way, and the table includes a number of examples.

The relation of atomic units to the corresponding SI units involves the values of the fundamental physical constants, and is therefore not exact. The numerical values in the table are based on the estimates of the appendix, Fundamental Constants. The numerical results of calculations in theoretical chemistry are frequently quoted in atomic units, or as numerical values in the form (*physical quantity*)/(*atomic unit*), so that the reader may make the conversion using the current best estimates of the physical constants.

Physical quantity	Name of unit	Symbol for unit	Value of unit in SI
mass	electron rest mass	m_e	$9.109\,3897\,(54) \times 10^{-31} \text{ kg}$
charge	elementary charge	e	$1.602\,177\,33\,(49) \times 10^{-19} \text{ C}$
action	Planck constant/ $2\pi^a$	\hbar	$1.054\,572\,66\,(63) \times 10^{-34} \text{ J s}$
length	bohr ^a	a_0	$5.291\,772\,49\,(24) \times 10^{-11} \text{ m}$
energy	hartree ^a	E_h	$4.359\,7482\,(26) \times 10^{-18} \text{ J}$
time		\hbar/E_h	$2.418\,884\,3341\,(29) \times 10^{-17} \text{ s}$
velocity ^b		$a_0 E_h/\hbar$	$2.187\,691\,42\,(10) \times 10^6 \text{ m s}^{-1}$
force		E_h/a_0	$8.238\,7295\,(25) \times 10^{-8} \text{ N}$
momentum, linear		\hbar/a_0	$1.992\,8534\,(12) \times 10^{-24} \text{ N s}$
electric current		$e E_h/\hbar$	$6.623\,6211\,(20) \times 10^{-3} \text{ A}$
electric field		E_h/ea_0	$5.142\,2082\,(15) \times 10^{11} \text{ V m}^{-1}$
electric dipole moment		ea_0	$8.478\,3579\,(26) \times 10^{-30} \text{ C m}$
magnetic flux density		\hbar/ea_0^2	$2.350\,518\,08\,(71) \times 10^5 \text{ T}$
magnetic dipole moment ^c		$e\hbar/m_e$	$1.854\,803\,08\,(62) \times 10^{-23} \text{ J T}^{-1}$

^a $\hbar = h/2\pi$; $a_0 = 4\pi\epsilon_0\hbar^2/m_e e^2$; $E_h = \hbar^2/m_e a_0^2$.

^bThe numerical value of the speed of light, when expressed in atomic units, is equal to the reciprocal of the fine structure constant α ; $c/(\text{au of velocity}) = \hbar/a_0 E_h = \alpha^{-1} \approx 137.035\,9895\,(61)$.

^cThe atomic unit of magnetic dipole moment is twice the Bohr magneton, μ_B .

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

Dimensionless Quantities

Values of dimensionless physical quantities, more properly called 'quantities of dimension one', are often expressed in terms of mathematically exactly defined values denoted by special symbols or abbreviations, such as % (per cent) and ppm (part per million). These symbols are then treated as units, and are used as such in calculations.

Fractions (Relative Values, Yields, Efficiencies)

Fractions such as relative uncertainty, mole fraction x (also called amount fraction, or number fraction), mass fraction w , and volume fraction ϕ , are sometimes expressed in terms of the symbols summarized in the table below.

Name	Symbol	Value	Examples
percent	%	10^{-2}	The isotopic abundance of carbon-13 expressed as a mole fraction is $x = 1.1\%$
part per million	ppm	10^{-6}	The relative uncertainty in the Planck constant $h (= 6.626\,0755(40) \times 10^{-34} \text{ J s})$ is 0.60 ppm The mass fraction of impurities in a sample of copper was found to be less than 3 ppm, $w < 3\text{ppm}$

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

These multiples of the unit one are not part of the SI and ISO recommends that these symbols should never be used. They are also frequently used as units of ‘concentration’ without a clear indication of the type of fraction implied (e.g. mole fraction, mass fraction or volume fraction). To avoid ambiguity they should only be used in a context where the meaning of the quantity is carefully defined. Even then, the use of an appropriate SI unit ratio may be preferred.

Deprecated Usage

Adding extra labels to ppm and similar symbols, such as ppmv (meaning ppm by volume) should be avoided. Qualifying labels may be added to symbols for physical quantities, but never to units.

The symbols % and ppm should not be used in combination with other units. In table headings and in labelling the axes of graphs the use of % and ppm in the denominator is to be avoided. Although one would write $x(^{13}\text{C}) = 1.1\%$, the notation $100x$ is to be preferred to $x/\%$ in tables and graphs.

The further symbols listed in the table below are also to be found in the literature, but their use is to be deprecated. Note that the names and symbols for 10^{-9} and 10^{-12} in this table are based on the American system of names. In other parts of the world a billion sometimes stands for 10^{12} and a trillion for 10^{18} . Note also that the symbol ppt is sometimes used for part per thousand, and sometimes for part per trillion.

To avoid ambiguity the symbols ppb, ppt and pphm should not be used.

Name	Symbol	Value	Examples
part per hundred	pph	10^{-2}	(Exactly equivalent to percent, %)
part per thousand	ppt	10^{-3}	Atmospheric carbon dioxide is depleted in carbon-13 mass fraction by 7‰ (or 7 ppt) relative to ocean water
permille ^a	‰	10^{-3}	
part per hundred million	pphm	10^{-8}	The mass fraction of impurity in the metal was less than 5 pphm
part per billion	ppb	10^{-9}	The air quality standard for ozone is a volume fraction of $\phi = 120 \text{ ppb}$
part per trillion	ppt	10^{-12}	The natural background volume fraction of NO in air was found to be $\phi = 140 \text{ ppt}$
part per quadrillion	ppq	10^{-15}	

^aThe permille is also spelled per mille, per mill, permil or pro mille.

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

9. FUNDAMENTAL PHYSICAL CONSTANTS

The following values were recommended by the CODATA Task Group on Fundamental Constants in 1986. For each constant the standard deviation uncertainty in the least significant digits is given in parentheses.

Quantity	Symbol	Value
Permeability of vacuum ^a	μ_0	$4\pi \times 10^{-7} \text{ H m}^{-1}$ (defined)
Speed of light in vacuum	c_0	$299\,792\,458 \text{ m s}^{-1}$ (defined)
Permittivity of vacuum ^a	$\varepsilon_0 = 1/\mu_0 c_0^2$	$8.854\,187\,816 \dots \times 10^{-12} \text{ F m}^{-1}$
Plank constant	h $\hbar = h/2\pi$	$6.626\,075\,5(40) \times 10^{-34} \text{ J s}$ $1.054\,572\,66(63) \times 10^{-34} \text{ J s}$
Elementary charge	e	$1.602\,177\,33(49) \times 10^{-19} \text{ C}$
Electron rest mass	m_e	$9.109\,389\,7(54) \times 10^{-31} \text{ kg}$
Proton rest mass	m_p	$1.672\,623\,1(10) \times 10^{-27} \text{ kg}$
Neutron rest mass	m_n	$1.674\,928\,6(10) \times 10^{-27} \text{ kg}$
Atomic mass constant, (unified atomic mass unit)	$m_u = 1 \text{ u}$	$1.660\,540\,2(10) \times 10^{-27} \text{ kg}$
Avogadro constant	L, N_A	$6.022\,136\,7(36) \times 10^{23} \text{ mol}^{-1}$
Boltzmann constant	K	$1.380\,658(12) \times 10^{-23} \text{ J K}^{-1}$
Faraday constant	F	$9.648\,530\,9(29) \times 10^4 \text{ C mol}^{-1}$
Gas constant	R	$8.314\,510(70) \text{ J K}^{-1} \text{ mol}^{-1}$
Zero of the Celsius scale		273.15 K (defined)
Molar volume, ideal gas, $p = 1 \text{ bar}$, $\theta = 0^\circ \text{C}$		$22.711\,08(19) \text{ l mol}^{-1}$
Standard atmosphere	atm	$101\,325 \text{ Pa}$ (defined)
Fine structure constant	$\alpha = \mu_0 e^2 c_0 / 2\hbar$ α^{-1}	$7.297\,353\,08(33) \times 10^{-3}$ $137.035\,989\,5(61)$
Bohr radius	$a_0 = 4\pi\varepsilon_0 \hbar^2 / m_e e^2$	$5.291\,772\,49(24) \times 10^{-11} \text{ m}$
Hartree energy	$E_h = \hbar^2 / m_e a_0^2$	$4.359\,748\,2(26) \times 10^{-18} \text{ J}$
Rydberg constant	$R_\infty = E_h / 2\hbar c_0$	$1.097\,373\,153\,4(13) \times 10^7 \text{ m}^{-1}$
Bohr magneton	$\mu_B = e\hbar / 2m_e$	$9.274\,0154(31) \times 10^{-24} \text{ J T}^{-1}$
Electron magnetic moment	μ_e	$9.284\,770\,1(31) \times 10^{-24} \text{ J T}^{-1}$
Landé g-factor for free electron	$g_e = 2\mu_e / \mu_B$	$2.002\,319\,304\,386(20)$
Nuclear magneton	$\mu_N = (m_e / m_p) \mu_B$	$5.050\,786\,6(17) \times 10^{-27} \text{ J T}^{-1}$
Proton magnetic moment	μ_p	$1.410\,607\,61(47) \times 10^{-26} \text{ J T}^{-1}$
Proton magnetogyric ratio	γ_p	$2.675\,221\,28(81) \times 10^8 \text{ s}^{-1} \text{ T}^{-1}$
Magnetic moment of protons in H_2O , μ'_p	μ'_p / μ_B	$1.520\,993\,129(17) \times 10^{-3}$
Proton resonance frequency per field in H_2O	$\gamma'_p / 2\pi$	$42.576\,375(13) \text{ MHz T}^{-1}$
Stefan-Boltzmann constant	$\sigma = 2\pi^5 k^4 / 15\hbar^3 c_0^2$	$5.670\,51(19) \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$
First radiation constant	$c_1 = 2\pi\hbar c_0^2$	$3.741\,7749(22) \times 10^{-16} \text{ W m}^2$
Second radiation constant	$c_2 = \hbar c_0 / k$	$1.438\,769(12) \times 10^{-2} \text{ m K}$
Gravitational constant	G	$6.672\,59(85) \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$
Standard acceleration of free fall	g_n	$9.806\,65 \text{ m s}^{-2}$ (defined)

^a $\text{H m}^{-1} = \text{N A}^{-2} = \text{N s}^2 \text{ C}^{-2}$; $\text{F m}^{-1} = \text{C}^2 \text{ J}^{-1} \text{ m}^{-1}$; ε_0 may be calculated exactly from the defined values of μ_0 and c_0 .

Values of Common Mathematical Constants

Mathematical constant	Symbol	Value
Ratio of circumference to diameter of a circle	π	3.141 592 653 59
Base of natural logarithms	e	2.718 281 828 46
Natural logarithm of 10	ln 10	2.302 585 092 99

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

10. IMPORTANT PEAKS IN THE MASS SPECTRA OF COMMON SOLVENTS

The following table gives the most important peaks that appear in the mass spectra of the most common solvents which might occur as an impurity in organic samples. The solvents are classified in ascending order of their M^+ peaks. The highest intensity peaks are indicated with (100%).¹⁻³

Important peaks in the mass spectra of common solvents

Solvents	Formula	M^+	Important peaks (m/z)
Water	H ₂ O	18 (100%)	17
Methanol	CH ₃ OH	32	31 (100%), 29, 15
Acetonitrile	CH ₃ CN	41 (100%)	40, 39, 38, 28, 15
Ethanol	CH ₃ CH ₂ OH	46	45, 31 (100%), 27, 15
Dimethyl ether	CH ₃ OCH ₃	46 (100%)	45, 29, 15
Acetone	CH ₃ COCH ₃	58	43 (100%), 42, 39, 27, 15
Acetic acid	CH ₃ CO ₂ H	60	45, 43, 18, 15
Ethylene glycol	HOCH ₂ CH ₂ OH	62	43, 33, 31 (100%), 29, 18, 15
Furan	C ₄ H ₄ O	68 (100%)	42, 39, 38, 37, 29, 18
Tetrahydrofuran	C ₄ H ₈ O	72	71, 43, 42 (100%), 41, 40, 39, 27, 18, 15
<i>n</i> -Pentane	C ₅ H ₁₂	72	57, 43 (100%), 42, 41, 39, 29, 28, 27, 15
Dimethylformamide (DMF)	HCON(CH ₃) ₂	73 (100%)	58, 44, 42, 30, 29, 28, 18, 15
Diethyl ether	(C ₂ H ₅) ₂ O	74	59, 45, 41, 31 (100%), 29, 27, 15
Methyl acetate	CH ₃ CO ₂ CH ₃	74	59, 43 (100%), 42, 32, 29, 28, 15
Carbon disulphide	CS ₂	76 (100%)	64, 44, 38, 32
Benzene	C ₆ H ₆	78 (100%)	77, 52, 51, 50, 39, 28
Pyridine	C ₅ H ₅ N	79 (100%)	80, 78, 53, 52, 51, 50, 39, 26
Dichloromethane	CH ₂ Cl ₂	84	86, 51, 49 (100%), 48, 47, 35, 28
Cyclohexane	C ₆ H ₁₂	84	69, 56, 55, 43, 42, 41, 39, 27
<i>n</i> -Hexane	C ₆ H ₁₄	86	85, 71, 69, 57 (100%), 43, 42, 41, 39, 29, 28, 27
<i>p</i> -Dioxane	C ₄ H ₈ O ₂	88 (100%)	87, 58, 57, 45, 43, 31, 30, 29, 28
Tetramethylsilane (TMS)	(CH ₃) ₄ Si	88	74, 73, 55, 45, 43, 29
1,2-Dimethoxyethane	(CH ₃ OCH ₂) ₂	90	60, 58, 45 (100%), 31, 29
Toluene	C ₆ H ₅ CH ₃	92	91 (100%), 65, 51, 39, 28
Chloroform	CHCl ₃	118	120, 83, 81, (100%), 47, 35, 28
Chloroform-d ₁	CDCl ₃	119	121, 84, 82 (100%), 48, 47, 35, 28
Carbon tetrachloride	CCl ₄	152 (not seen)	121, 119, 117 (100%), 84, 82, 58.5, 47, 35, 28
Tetrachloroethene	CCl ₂ =CCl ₂	164 (not seen)	168, 166 (100%), 165, 164, 131, 128, 129, 95, 94, 82, 69, 59, 47, 31, 24

11. NOMENCLATURE AND TERMINOLOGY FOR ANALYTICAL PYROLYSIS (IUPAC RECOMMENDATIONS 1993)

Prepared for publication by

P. C. Uden, University of Massachusetts, Amherst, MA, USA

© 1993 IUPAC

Abstract

This paper defines terms and definitions used in analytical methods of pyrolysis and includes expressions for coupled systems and for the description of the temperature profiles and the products that are obtained.

Introduction

Thermal degradation under controlled conditions is often used as part of an analytical procedure, either to render a sample into a suitable form for subsequent analysis by gas chromatography, mass spectrometry or infrared spectroscopy or by direct monitoring as an analytical technique in its own right. A range of terms and expression have been used in the field and this nomenclature brings these together in a systematic manner and assigns each a specific meaning.

Analytical Pyrolysis

Analytical Pyrolysis

The characterization, in an inert atmosphere, of a material or a chemical process by a chemical degradation reaction(s) induced by thermal energy.

Catalytic Pyrolysis

A pyrolysis that is influenced by the addition of a catalyst.

Char

A solid carbonaceous pyrolysis residue.

Coil Pyrolyser

A pyrolyser in which the sample (sometimes located in a tubular vessel) is placed in a metal coil that is heated to cause pyrolysis.

Continuous Mode (Furnace) Pyrolyser

A pyrolyser in which the sample is introduced into a furnace preheated to the final temperature.

Curie-Point Pyrolyser

A pyrolyser in which a ferromagnetic sample carrier is inductively heated to its Curie point.

Filament (Ribbon) Pyrolyser

A pyrolyser in which the sample is placed on a metal filament (ribbon) that is resistively heated to cause pyrolysis.

Final Pyrolysis Temperature ($T_{(f,Py)}$)

The final (steady state) temperature which is attained by a pyrolyser. (The terms 'equilibrium temperature' and 'pyrolysis temperature' may be used when referring to an isothermal pyrolysis; they are not recommended for use with a non-isothermal pyrolysis.)

Flash Pyrolysis

A pyrolysis that is carried out with a fast rate of temperature increase, of the order of 10 000 K/s.

Fractionated Pyrolysis

A pyrolysis in which the same sample is pyrolysed at different temperatures for different times in order to study special fractions of the sample.

In-Source Pyrolysis

A pyrolysis in which the reactor is located within the ion source of a mass spectrometer.

IR-Pyrogram

Chromatogram of a pyrolysate detected by infrared spectrometry.

Isothermal Pyrolysis

A pyrolysis during which the temperature is essentially constant.

Maximum Pyrolysis Temperature ($T_{(max,Py)}$)

The highest temperature in a temperature/time profile.

MS-Pyrogram

Chromatogram of a pyrolysate detected by mass spectrometry.

Off-Line Pyrolysis

A pyrolysis in which the products are trapped before analysis.

Oxidative Pyrolysis

A pyrolysis that occurs in the presence of an oxidative atmosphere.

Pressure Monitored Pyrolysis

A pyrolysis technique in which the pressure of the volatile pyrolysates is recorded as the sample is heated.

Pulse Mode Pyrolyser

A pyrolyser in which the sample is introduced into a cold furnace which is then heated rapidly.

Pyrogram

A chromatogram of a pyrolysate.

Pyrolysate (Pyrolyzate)

The products of pyrolysis.

Pyrolyser (Pyrolyzer)

A device for performing pyrolysis.

Pyrolysis

A chemical degradation reaction that is caused by thermal energy. The term *pyrolysis* generally refers to an inert environment.)

Pyrolysis-Gas Chromatography (Py-GC)

A pyrolysis technique in which the volatile pyrolysates are directly conducted into a gas chromatograph for separation and detection.

Pyrolysis-Gas Chromatograph-Mass Spectrometry (Py-GC-MS)

A pyrolysis technique in which the volatile pyrolysates are separated and analysed by on-line gas chromatography-mass spectrometry.

Pyrolysis-Gas Chromatography-Infrared Spectroscopy (Py-GC-IR)

A pyrolysis technique in which the volatile pyrolysates are separated and analysed by on-line gas chromatography-infrared spectroscopy.

Pyrolysis-Infrared Spectroscopy (Py-IR)

A pyrolysis technique in which the pyrolysates are detected and analysed by on-line infrared spectroscopy.

Pyrolysis-Infrared Spectrum

Infrared spectrum obtained from *pyrolysis-infrared spectroscopy*.

Pyrolysis-Mass Spectrometry (Py-MS)

A pyrolysis technique in which the volatile pyrolysates are detected and analysed by on-line mass spectrometry.

Pyrolysis-Mass Spectrum

Mass spectrum obtained from *pyrolysis-mass spectrometry*.

Pyrolysis Reactor

That portion of the pyrolyser in which the pyrolysis takes place.

Pyrolysis Residue

That portion of the pyrolysate that does not leave the reactor.

Pyrolysis Thermogram

The result of a temperature programmed pyrolysis in which the detector signals, e.g. total ion current or single ions, total absorbance or a GC-detector, are plotted against time or temperature.

Reductive Pyrolysis

A pyrolysis which occurs in the presence of a reducing atmosphere.

Sequential Pyrolysis

A pyrolysis in which the same initial sample is repetitively pyrolysed under identical conditions (final pyrolysis temperature, temperature rise time and total heating time).

Stepwise Pyrolysis

A pyrolysis in which the sample temperature is raised stepwise. The pyrolysis products are recorded between each step.

Tar

A liquid pyrolysis residue.

Temperature-Programmed Pyrolysis

A pyrolysis during which the sample is heated at a controlled rate within a temperature range in which pyrolysis occurs.

Temperature Rise Time (TRT)

The time required for a pyrolyser temperature to be increased from its initial to its final temperature.

Temperature Time Profile (TTP)

A graphical representation of temperature *versus* time for a particular pyrolysis experiment or pyrolyser.

Total heating time (THT)

The time between the onset and conclusion of the sample heating in a pyrolysis experiment.

Volatile Pyrolyzate

That portion of the pyrolystate which has adequate vapour pressure to reach the detector.

List of Symbols

$T_{(f,Py)}$	Final pyrolysis temperature
$T_{(max,Py)}$	Maximum pyrolysis temperature

Index of Acronyms

Py-GC	Pyrolysis-gas chromatography
Py-GC-IR	Pyrolysis-gas chromatography-infrared spectroscopy
Py-GC-MS	Pyrolysis-gas chromatography-mass spectrometry
Py-IR	Pyrolysis-infrared spectroscopy
Py-MS	Pyrolysis-mass spectrometry
THT	Total heating time
TRT	Temperature rise time
TTP	Temperature time profile

12A. NOMENCLATURE

Chromatography (IUPAC Recommendations 1993)

Prepared for publication by

L. S. Ettre, Yale University, New Haven, CT, USA

© 1993 IUPAC

Abstract

This report presents definitions of terms and symbols used in all chromatographic separations. The reports covers gas, liquid, size-exclusion, ion-exchange and supercritical-fluid chromatography and both column and planar modes of separation. Definitions are included for the description of the separation process, the chromatographic system and equipment and the properties of detectors.

Introduction

The Commission on Analytical Nomenclature of IUPAC has been active for a long time in establishing nomenclatures for chromatography. After proposing suitable nomenclatures for gas chromatography [1–2] and ion exchange [3–4] the Commission developed a unified nomenclature for chromatography [5–6]. Parallel to these activities other standardization bodies and scientists have also dealt with nomenclatures on gas chromatography [7–15], supercritical-fluid chromatography [16], liquid chromatography [17–20], exclusion chromatography [21–23] and planar chromatography [24].

The original activities of the IUPAC Commission on Analytical Nomenclature aimed to create a unified nomenclature applicable to all forms of chromatography, took place over 20 years ago. Since that time chromatographic techniques have advanced significantly. Based on these developments it was decided to prepare a new, up-to-date universal chromatography nomenclature, which also considers the recommendations incorporated in the various other nomenclatures developed since the original work of IUPAC.

The present nomenclature was prepared by Dr. L. S. Ettre originally for the Commission on Analytical Nomenclature. Following the reorganization of the Commissions of the Analytical Division at the General Assembly in Lund in 1989, this project became the responsibility of the Commission on Chromatography and Other Analytical Separations (LLTC). The Nomenclature considers all the previous nomenclatures referenced above as well as the four publications dealing with these nomenclatures [25–27].

The present nomenclature deals with all chromatographic terms and definitions used in the major chromatographic techniques such as gas, liquid and supercritical-fluid chromatography, column and planar chromatography, partition, adsorption, ion-exchange and exclusion chromatography. However, it does not include terms related to the results calculated from chromatography data such as e.g. the various molecular weight terms computed from the primary data obtained by exclusion chromatography. Also it does not deal with detailed information related to detection and detectors or the relationships between chemical structure and chromatographic retention.

General Rules

In developing the unified nomenclature the rules and recommendations set up by IUPAC's Division of Physical Chemistry [28] were followed. According to these, the following symbols should be used for major physical and physico-chemical quantities and units:

area	A
density	ρ
diameter	d
diffusion coefficient	D
equilibrium constant	K
mass (weight)	W
pressure	p or P
radius	r
rate constant	k
temperature (kelvin)	T
time	t
velocity	u
viscosity	η
volume	V

The only deviation from the rules set by the Division of Physical Chemistry of IUPAC is the use of L (instead of l) for length. The reason for this is the easy interchangeability in a printed, and particularly typed, text of the

letter l with the numeral 'one'. Additional basic symbols accepted were F for the volumetric flow rates and w for the peak widths. Also, differentiation has been made between p (for pressures) and P (for relative pressure).

In addition to these basic rules the following additional rules are followed in the present proposal:

- (a) Except for a few superscripts further differentiation is always made by using subscripts and never composite symbols.
- (b) Superscripts are used for various retention times and volumes and to specifically indicate data obtained in programmed-temperature conditions.
- (c) Subscripts referring to the physical conditions or the phase are capitalized, e.g. M and S for the mobile and stationary phases respectively, or, in gas chromatography, G for the gas and L for the liquid phase. Thus, e.g. the diffusion coefficient in the mobile phase is D_M and not D_m .
- (d) In addition to those mentioned above, a few capitalized subscripts are used such as R for 'retention' (as in t_R and V_R), N for 'net' (as in t_N and V_N) and F in R_F , the retardation factor used in planar chromatography.
- (e) Compound subscripts are avoided. If a given compound is indicated and there is already a subscript, and if the compound is characterized by more than a simple number or letter, then the new subscript should be in parentheses. Thus, while it is $t_{R,i}$, it should be $t_{R(st)}$ or $t_{R(z+1)}$.
- (f) In addition to reference to the outlet of a column, subscript 'o' is also used in a number of terms to describe some fundamental values. Similarly subscript 'i' has various meanings, depending on the term in which it is used.
- (g) Physical parts of the system are generally characterized by lower-case subscripts such as, c for column, p for particles or pores, and f for film.

Three tables follow the nomenclature, listing alphabetically the terms, symbols and acronyms included in the text.

Contents

1. General Terminology

- 1.1. Basic Definitions
- 1.2. Principal Methods
- 1.3. Classification According to the Shape of the Chromatographic Bed
- 1.4. Classification According to the Physical State of the Mobile Phase
- 1.5. Classification According to the Mechanism of Separation
- 1.6. Special Techniques

2. Terms Related to the Chromatographic System

- 2.1. Apparatus in Column Chromatography
- 2.2. Apparatus in Planar Chromatography

3. Terms Related to the Chromatographic Process and the Theory of Chromatography

- 3.1. The Chromatographic Medium
- 3.2. The Column
- 3.3. The Chromatogram
- 3.4. Diffusion
- 3.5. Temperatures
- 3.6. The Mobile Phase
- 3.7. Retention Parameters in Column Chromatography
- 3.8. Retention Parameters in Planar Chromatography
- 3.9. Distribution Constants
- 3.10. Terms Expressing the Efficiency of Separation

4. Terms Related to Detection

- 4.1. Classification of Detectors
- 4.2. Detector Response

- 4.3. Noise and Drift
- 4.4. Minimum Detectability
- 4.5. Linear and Dynamic Ranges

5. Special Terminology Used in Ion-exchange Chromatography

- 5.1. Basic Definitions
- 5.2. The Mobile Phase
- 5.3. The Chromatographic Medium
- 5.4. Capacity Values
- 5.5. Diffusion, Selectivity and Separation
- 5.6. Distribution Constants

6. Special Terminology Used in Exclusion Chromatography

- 6.1. The Column
- 6.2. Retention Parameters
- 6.3. Efficiency Terms

- 6. Determination of the Linear and Dynamic Ranges of a Chromatographic Detector
- 7. Retention Characteristics in Exclusion Chromatography

1. General Terminology

1.1. Basic Definitions

1.1.01. Chromatography Chromatography is a physical method of separation in which the components to be separated are distributed between two phases, one of which is stationary (stationary phase) while the other (the mobile phase) moves in a definite direction.

1.1.02. Chromatogram A graphical or other presentation of detector response, concentration of analyte in the effluent or other quantity used as a measure of effluent concentration versus effluent volume or time. In planar chromatography “chromatogram” may refer to the paper or layer with the separated zones.

1.1.03. Chromatograph (verb) To separate by chromatography.

1.1.04. Chromatograph (noun) The assembly of apparatus for carrying out chromatographic separation.

1.1.05. Stationary phase The stationary phase is one of the two phases forming a chromatographic system. It may be a solid, a gel or a liquid. If a liquid, it may be distributed on a solid. This solid may or may not contribute to the separation process. The liquid may also be chemically bonded to the solid (*Bonded Phase*) or immobilized onto it (*Immobilized Phase*).

The expression *Chromatographic Bed* or *Sorbent* may be used as a general term to denote any of the different forms in which the stationary phase is used.

Note: Particularly in gas chromatography where the stationary phase is most often a liquid, the term *Liquid Phase* is used for it as compared to the *Gas Phase*, i.e. the mobile phase. However, particularly in the

early development of liquid chromatography, the term 'liquid phase' had also been used to characterize the mobile phase as compared to the 'solid phase' i.e. the stationary phase. Due to this ambiguity, the use of the term 'liquid phase' is discouraged. If the physical state of the stationary phase is to be expressed, the use of the adjective forms such as *Liquid Stationary Phase* and *Solid Stationary Phase*, *Bonded Phase* or *Immobilized Phase* is proposed.

1.1.05.1. Bonded phase A stationary phase which is covalently bonded to the support particles or to the inside wall of the column tubing.

1.1.05.2. Immobilized phase A stationary phase which is immobilized on the support particles, or on the inner wall of the column tubing, e.g. by *in situ* polymerization (cross-linking) after coating.

1.1.06. Mobile phase A fluid which percolates through or along the stationary bed, in a definite direction. It may be a liquid (*Liquid Chromatography*) or a gas (*Gas Chromatography*) or a supercritical fluid (*Supercritical-Fluid Chromatography*). In gas chromatography the expression *Carrier Gas* may be used for the mobile phase. In elution chromatography the expression *Eluent* is also used for the mobile phase.

1.1.07. Elute (verb) To chromatograph by elution chromatograph. The process of elution may be stopped while all the sample components are still on the chromatographic bed or continued until the components have left the chromatographic bed.

Note: The term 'elute' is preferred to the term *Develop* used in former nomenclatures of planar chromatography.

1.1.08. Effluent The mobile phase leaving the column.

1.1.09. Sample The mixture consisting of a number of components the separation of which is attempted on the chromatographic bed as they are carried or eluted by the mobile phase.

1.1.10. Sample components The chemically pure constituents of the sample. They may be unretained (i.e. not delayed) by the stationary phase, partially retained (i.e. eluted at different times) or retained permanently. The terms *Elute* or *Analyte* are also acceptable for a sample component.

1.1.11. Solute A term referring to the sample components in partition chromatography.

1.1.12. Solvent A term sometimes referring to the liquid stationary phase in partition chromatography.

Note: In liquid chromatography the term 'solvent' has been often used for the mobile phase. This usage is not recommended.

1.1.13. Zone A region in the chromatographic bed where one or more components of the sample are located. The term *Band* may also be used for it.

1.2. Principal Methods

1.2.01. Frontal chromatography A procedure in which the sample (liquid or gas) is fed continuously into the chromatographic bed. In frontal chromatography no additional mobile phase is used.

1.2.02. Displacement chromatography A procedure in which the mobile phase contains a compound (*the Displacer*) more strongly retained than the components of the sample under examination. The sample is fed into the system as a finite slug.

1.2.03. Elution chromatography A procedure in which the mobile phase is continuously passed through or along the chromatographic bed and the sample is fed into the system as a finite slug.

1.3. Classification According to the Shape of the Chromatographic Bed

1.3.01. Column chromatography A separation technique in which the stationary bed is within a tube. The particles of the solid stationary phase or the support coated with a liquid stationary phase may fill the whole inside volume of the tube (*Packed Column*) or be concentrated on or along the inside tube wall leaving an open, unrestricted path for the mobile phase in the middle part of the tube (*Open-Tubular Column*).

1.3.02. Planar chromatography A separation technique in which the stationary phase is present as or on a plane. The plane can be a paper, serving as such or impregnated by a substance as the stationary bed (*Paper Chromatography*, PC) or a layer of solid particles spread on a support, e.g. a glass plate (*Thin-Layer Chromatography*, TLC). Sometimes planar chromatography is also termed *Open-Bed Chromatography*.

1.4. Classification According to the Physical State of the Mobile Phase

1.4.01. Chromatographic techniques are often classified by specifying the physical state of *both* phases used. Accordingly, the following terms are in use:

Gas-liquid chromatography (GLC)
 Gas-solid chromatography (GSC)
 Liquid-Liquid chromatography (LLC)
 Liquid-solid chromatography (LSC)

The term *Gas-Liquid Partition Chromatography* (GLPC) can also be found in the literature. However, often distinction between these modes is not easy. For example, in GC, a liquid may be used to modify an adsorbent-type solid stationary phase.

1.4.02. Gas chromatography (GC) A separation technique in which the mobile phase is a gas. Gas chromatography is always carried out in a column.

1.4.03. Liquid chromatography (LC) A separation technique in which the mobile phase is a liquid. Liquid chromatography can be carried out either in a column or on a plane.

Note: Present-day liquid chromatography generally utilizing very small particles and a relatively high inlet pressure is often characterized by the term *High-Performance* (or *High-Pressure*) *Liquid Chromatography*, and the acronym HPLC.

1.4.04. Supercritical-fluid chromatography (SFC) A separation technique in which the mobile phase is a fluid above and relatively close to its critical temperature and pressure.

Note: In general the terms and definitions used in gas or liquid chromatography are equally applicable to supercritical-fluid chromatography.

1.5. Classification According to the Mechanism of Separation

1.5.01. Adsorption chromatography Separation is based mainly on differences between the adsorption affinities of the sample components for the surface of an active solid.

1.5.02. Partition chromatography Separation is based mainly on differences between the solubilities of the sample components in the stationary phase (gas chromatography), or on differences between the solubilities of the components in the mobile and stationary phases (liquid chromatography).

1.5.03. Ion-exchange chromatography Separation is based mainly on differences in the ion exchange affinities of the sample components.

Note: Present day ion-exchange chromatography on small particle high efficiency columns and usually utilising conductometric or spectroscopic detectors is often referred to as *Ion Chromatography* (IC).

1.5.04. Exclusion chromatography Separation is based mainly on exclusion effects, such as differences in molecular size and/or shape or in charge. The term *Size-Exclusion Chromatography* may also be used when separation is based on molecular size. The terms *Gel Filtration* and *Gel-Permeation Chromatography* (GPC) were used earlier to describe this process when the stationary phase is a swollen gel. The term *Ion-Exclusion Chromatography* is specifically used for the separation of ions in an aqueous phase.

1.5.05. Affinity chromatography This expression characterizes the particular variant of chromatography in which the unique biological specificity of the analyte and ligand interaction is utilized for the separation.

1.6. Special Techniques

1.6.01. Reversed-phase chromatography An elution procedure used in liquid chromatography in which the mobile phase is significantly more polar than the stationary phase, e.g. a microporous silica-based material with chemically bonded alkyl chains.

Note: The term “reverse phase” is an incorrect expression to be avoided.

1.6.02. Normal-phase chromatography An elution procedure in which the stationary phase is more polar than the mobile phase. This term is used in liquid chromatography to emphasize the contrast to reversed-phase chromatography.

1.6.03. Isocratic analysis The procedure in which the composition of the mobile phase remains constant during the elution process.

1.6.04. Gradient elution The procedure in which the composition of the mobile phase is changed continuously or stepwise during the elution process.

1.6.05. Stepwise elution The elution process in which the composition of the mobile phase is changed in steps during a single chromatographic run.

1.6.06. Two-dimensional chromatography A procedure in which parts or all of the separated sample components are subjected to additional separation steps. This can be done, e.g. by conducting a particular fraction eluting from the column into another column (system) having different separation characteristics. When combined with additional separation steps, this may be described as *Multi-Dimensional Chromatography*.

In planar chromatography two-dimensional chromatography refers to the chromatographic process in which the components are caused to migrate first in one direction and subsequently in a direction at right angles to the first one; the two elutions are carried out with different eluents.

1.6.07. Isothermal chromatography A procedure in which the temperature of the column is kept constant during the separation.

1.6.08. Programmed-temperature chromatography (temperature programming) A procedure in which the temperature of the column is changed systematically during a part or the whole of the separation.

1.6.09. Programmed-flow chromatography (flow programming) A procedure in which the rate of flow of the mobile phase is changed systematically during a part or the whole of the separation.

1.6.10. Programmed-pressure chromatography (pressure programming) A procedure in which the inlet pressure of the mobile phase is changed systematically during a part or whole of the separation.

1.6.11. Reaction chromatography A technique in which the identities of the sample components are intentionally changed between sample introduction and detection. The reaction can take place upstream of the column when the chemical identity of the individual components passing through the column differs from that of the original sample, or between the column and the detector when the original sample components are separated in the column but their identity is changed prior to entering the detection device.

1.6.11.1. Pyrolysis-gas chromatography A version of reaction chromatography in which a sample is thermally decomposed to simpler fragments before entering the column.

1.6.11.2. Post-column derivatization A version of reaction chromatography in which the separated sample components eluting from the column are derivatized prior to entering the detector. The derivatization process is generally carried out “on-the-fly”, i.e. during transfer of the sample components from the column to the detector. Derivatization may also be carried out before the sample enters the column or the planar medium; this is *pre-column (preliminary) derivatization*.

2. Terms Related to the Chromatographic System

2.1. Apparatus in Column Chromatography

2.1.01. Pump A device designed to deliver the mobile phase at a controlled flow-rate to the separation system. Pumps are generally used in liquid chromatography.

2.1.01.1. Syringe pumps Pumps with a piston, which advances at a controlled rate within a smooth cylinder to displace the mobile phase.

2.1.01.2. Reciprocating pumps Pumps with a single or multiple chamber, from which the mobile phase is displaced by reciprocating piston(s) or diaphragm(s).

2.1.01.3. Pneumatic pumps Pumps which employ a gas to displace the liquid mobile phase either directly or via a piston.

2.1.02. Sample injector A device by which a liquid, solid or gaseous sample is introduced into the mobile phase of the chromatographic bed.

2.1.02.1. Direct injector A device which directly introduces the sample into the mobile-phase stream.

2.1.02.2. Bypass injector A device in which the sample is first introduced into a chamber (loop), temporarily isolated from the mobile phase system by valves, which can be switched to make an instantaneous diversion of the mobile phase stream through the chamber to carry the sample to the column. A bypass injector may also be known as a *Valve Injector* or *Sampling Valve* (see 2.1.02.7).

2.1.02.3. On-column injector A device in which the sample is directly introduced into the column. In gas chromatography the on-column injector permits the introduction of the liquid sample into the column without prior evaporation.

2.1.02.4. Flash vaporizer A heated device used in gas chromatography. Here the liquid sample is introduced into the carrier gas stream with simultaneous evaporation and mixing with the carrier gas prior to entering the column.

2.1.02.5. Split injection A sample introduction technique used in gas chromatography. The sample is flash vaporized and after thorough mixing of the sample with carrier gas, the stream is split into two portions, one being conducted to the column and the other being discarded.

2.1.02.6. Programmed temperature vaporizer (PTV) A sample introduction device used in gas chromatography. The liquid sample is introduced, usually with a syringe, into a device similar to a flash vaporizer, the temperature of which is kept low, below the boiling point of the sample components. After withdrawal of the syringe, the device is heated up very rapidly in a controlled fashion to evaporate the sample into the continuously flowing carrier gas stream. The PTV may also be used in the split mode: in this case, the carrier gas stream containing the evaporated sample components is split into two portions, one of which is conducted into the column while the other is discarded.

2.1.02.7. Gas sampling valve A bypass injector permitting the introduction of a gaseous sample of a given volume into a gas chromatograph.

2.1.03. Column oven A thermostatically controlled oven containing the column, the temperature of which (*Separation Temperature* or *Column Temperature*) can be varied within a wide range.

2.1.04. Fraction collector A device for recovering fractional volumes of the column effluent.

2.1.05. Detector A device that measures the change in the composition of the eluent by measuring physical or chemical properties.

2.2. Apparatus in Planar Chromatography

2.2.01. Spotting device The syringe or micropipet used to deliver a fixed volume of sample as a spot or streak to the paper or thin-layer media at the origin.

2.2.02. Elution chamber (developing chamber) A closed container, the purpose of which is to enclose the media used as well as the mobile phase to maintain a constant environment in the vapor phase.

2.2.02.1. Sandwich chamber A chamber in which the walls are close enough to the paper or plate to provide a relatively fast equilibration.

2.2.02.2. Ascending elution (ascending development) A mode of operation in which the paper or plate is in a vertical or slanted position and the mobile phase is supplied to its lower edge; the upward movement depends on capillary action.

2.2.02.3. Horizontal elution (horizontal development) A mode of operation in which the paper or plate is in a horizontal position and the mobile-phase movement along the plane depends on capillary action.

2.2.02.4. Descending elution (descending development) A mode of operation in which the mobile phase is supplied to the upper edge of the paper or plate and the downward movement is governed mainly by gravity.

2.2.02.5. Radial elution (radial development) or circular elution (circular development) A mode of operation in which the sample is spotted at a point source at or near the middle of the plane and is carried outward in a circle by the mobile phase, also applied at that place.

2.2.02.6. Anticircular elution (anticircular development) The opposite of 2.2.02.5. Here the sample as well as the mobile phase is applied at the periphery of a circle and both move towards the center.

2.2.02.7. Chamber saturation (saturated development) This expression refers to the uniform distribution of the mobile phase vapor through the elution chamber prior to chromatography.

2.2.02.8. Unsaturated elution (unsaturated development) This expression refers to chromatography in an elution chamber without attaining chamber saturation.

2.2.02.9. Equilibration The expression refers to the level of saturation of the chromatographic bed by the mobile-phase vapor prior to chromatography.

2.2.03. Visualization chamber A device in which the planar media may be viewed under controlled-wavelength light, perhaps after spraying with chemical reagents to render the separated components as visible spots under specified conditions.

2.2.04. Densitometer A device which allows portions of the developed paper or thin-layer media to be scanned with a beam of light of a specified wavelength for measurements of UV or visible light absorption or fluorescence, providing values which can be used for the quantisation of the separated compounds.

3. Terms Related to the Chromatographic Process and the Theory of Chromatography

3.1. The Chromatographic Medium

3.1.01. **Active solid** A solid with sorptive properties.

3.1.02. **Modified active solid** An active solid the sorptive properties of which have been changed by some treatment.

3.1.03. **Solid support** A solid that holds the stationary phase but, ideally, does not contribute to the separation process.

3.1.04. **Binders** Additives used to hold the solid stationary phase to the inactive plate or sheet in thin-layer chromatography.

3.1.05. **Gradient layer** The chromatographic bed used in thin-layer chromatography in which there is a gradual transition in some property.

3.1.06. **Impregnation** The modification of the separation properties of the chromatographic bed used in planar chromatography by appropriate additives.

3.1.07. **Packing** The active solid, stationary liquid plus solid support, or swollen gel contained in a tube.

3.1.07.1. *Totally porous packing* Here the stationary phase permeates each porous particle.

3.1.07.2. *Pellicular packing* In this case the stationary phase forms a porous outer shell on an impermeable particle.

3.1.08. **Particle diameter (d_p)** The average diameter of the solid particles.

3.1.09. **Pore radius (r_p)** The average radius of the pores within the solid particles.

3.1.10. **Liquid-phase loading** A term used in partition chromatography to express the relative amount of the liquid stationary phase in the column packing. It is equal to the mass fraction (%) of liquid stationary phase in the total packing (liquid stationary phase plus support).

3.2. The Column

3.2.01. **Column** The tube and the stationary phase contained within, through which the mobile phase passes.

3.2.02. **Packed column** A tube containing a solid packing.

3.2.03. **Open-tubular column** A column, usually having a small diameter in which either the inner tube wall, or a liquid or active solid held stationary on the tube wall acts as the stationary phase and there is an open, unrestricted path for the mobile phase.

3.2.03.1. *Wall-coated open-tubular (WCOT) column* In these columns the liquid stationary phase is coated on the essentially unmodified smooth inner wall of the tube.

3.2.03.2. *Porous-layer open-tubular (PLOT) column* In these columns there is a porous layer on the inner wall. Porosity can be achieved by either chemical means (e.g. etching) or by the deposition of porous particles on the wall from a suspension. The porous layer may serve as a support for a liquid stationary phase or as the stationary phase itself.

3.2.03.3. Support-coated open-tubular (SCOT) column A version of a PLOT column in which the porous layer consists of support particles and was deposited from a suspension.

3.2.04. Capillary column A general term for columns having a small diameter. A capillary column may contain a packing or have the stationary phase supported on its inside wall. The former case corresponds to a *Packed Capillary Column* while the latter case corresponds to an *Open-Tubular Column*. Due to the ambiguity of this term its use without an adjective is discouraged.

3.2.05. Column volume (V_c) The geometric volume of the part of the tube that contains the packing:

$$V_c = A_c L$$

where A_c is the internal cross-sectional area of the tube and L is the length of the packed part of the column.

In the case of wall-coated open-tubular columns the column volume corresponds to the geometric volume of the whole tube having a liquid or a solid stationary phase on its wall.

3.2.06. Bed volume Synonymous with *Column Volume* for a packed column.

3.2.07. Column diameter (d_c) The inner diameter of the tubing.

3.2.08. Column radius (r_c) The inside radius of the tubing.

3.2.09. Column length (L) The length of that part of the tube which contains the stationary phase.

3.2.10. Cross-sectional area of the column (A_c) The cross-sectional area of the empty tube:

$$A_c = \pi r_c^2 = \pi (d_c/2)^2$$

3.2.11. Interparticle volume of the column (V_o) The volume occupied by the mobile phase between the particles in the packed section of a column. It is also called the *Interstitial Volume* or the *Void Volume* of the column.

3.2.11.1. In liquid chromatography, the interparticle volume is equal to the mobile-phase hold-up volume (V_M) in the ideal case, neglecting any extra-column volume.

3.2.11.2. In gas chromatography, the symbol V_G may be used for the interparticle volume of the column. In the ideal case, neglecting any extra-column volume, V_G is equal to the corrected gas hold-up volume (V_M^o) (see 3.6.03 and 3.7.04):

$$V_G = V_M^o = V_M \cdot j$$

3.2.12. Interparticle porosity (ε) The interparticle volume of a packed column per unit column volume:

$$\varepsilon = V_o/V_c$$

It is also called the *Interstitial Fraction* of the column.

3.2.13. Extra-column volume The volume between the effective injection point and the effective detection point, excluding the part of the column containing the stationary phase. It is composed of the volumes of the injector, connecting lines and detector.

3.2.13.1. Dead-volume This term is also used to express the extra-column volume. Strictly speaking, the term “dead-volume” refers to volumes within the chromatographic system which are not swept by the mobile phase. On the other hand, mobile phase is flowing through most of the extra-column volumes. Due to this ambiguity the use of the term “dead-volume” is discouraged.

3.2.14. Liquid-phase film thickness (d_f) A term used in connection with open-tubular columns to express the average thickness of the liquid stationary phase film coated on the inside wall of the tubing.

3.2.15. Stationary-phase volume (V_s) The volume of the liquid stationary phase or the active solid in the column. The volume of any solid support is not included. In the case of partition chromatography with a liquid stationary phase, it is identical to the *Liquid-Phase Volume* (V_L).

3.2.16. Mass (weight) of the stationary phase (W_s) The mass (weight) of the liquid stationary phase or the active solid in the column. The mass (weight) of any solid support is not included. In the case of partition chromatography with a liquid stationary phase it is identical to the *Liquid Phase Mass (Weight)* (W_L).

3.2.17. Phase ratio (β) The ratio of the volume of the mobile phase to that of the stationary phase in a column:

$$\beta = V_o/V_s$$

In the case of open-tubular columns the geometric internal volume of the tube (V_c) is to be substituted for V_o .

3.2.18. Specific permeability (B_o) A term expressing the resistance of an empty tube or packed column to the flow of a fluid (the mobile phase). In the case of a packed column

$$B_o = \frac{d_p^2 \varepsilon^3}{180(1 - \varepsilon)^2} \approx \frac{d_p^2}{1000}$$

In the case of an open-tubular column

$$B_o = \frac{r_c^2}{8}$$

3.2.19. Flow resistance parameter (Φ) This term is used to compare packing density and permeability of columns packed with different particles; it is dimensionless.

$$\Phi = d_p^2/B_o$$

where d_p is the average particle diameter. In open-tubular columns $\Phi = 32$.

3.3. The Chromatogram

3.3.01. Differential chromatogram A chromatogram obtained with a differential detector (see Figure 1A).

3.3.02. Integral chromatogram A chromatogram obtained with an integral detector (see Figure 1B).

Figure 1 Typical chromatogram: A, differential record produced by differential detector; B, integral record produced by integral detector.

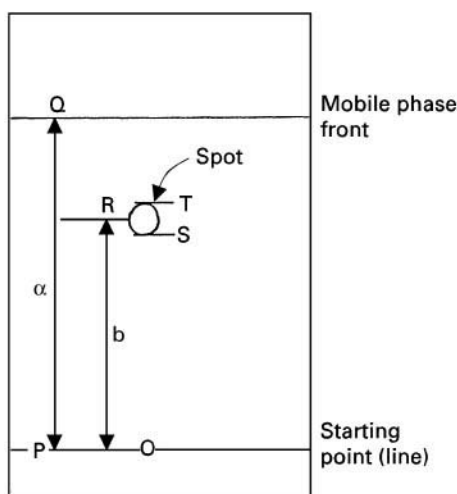

Figure 2 Typical planar chromatogram.

3.3.03. Starting point or line The point or line on a chromatographic paper or layer where the substance to be chromatographed is applied (P in Figure 2).

3.3.04. Spot A zone in paper and thin-layer chromatography of approximately circular appearance.

3.3.04.1. Spot diameter (ST in Figure 2) The width of the sample component spot before or after chromatography.

3.3.05. Baseline The portion of the chromatogram recording the detector response when only the mobile phase emerges from the column.

3.3.06. Peak The portion of a differential chromatogram recording the detector response when a single component is eluted from the column (see Figure 1A). If separation is incomplete, two or more components may be eluted as one *Unresolved Peak*.

3.3.06.1. Peak base (CP in Figure 1A) The interpolation of the baseline between the extremities of the peak.

3.3.06.2. Peak area (CHFEGJP in Figure 1A) The area enclosed between the peak and the peak base.

3.3.06.3. Peak maximum (E in Figure 1A) The point on the peak at which the distance to the peak base, measured in a direction parallel to the axis representing detector response, is a maximum.

3.3.06.4. Peak height (EB in Figure 1A) The distance between the peak maximum and the peak base, measured in a direction parallel to the axis representing detector response.

3.3.06.5. Standard deviation (σ) The term in the exponent of the equation relating the width and height of a Gaussian peak:

$$y = y_o \cdot \exp. - \left[\frac{x^2}{2\sigma^2} \right]$$

where y is the peak height at any point on the peak, y_o is the peak height at maximum, x is the distance from the ordinate (i.e. half of the width at that point), and σ is the standard deviation of the peak. In practice, the standard deviation can be calculated from one of the peak-width values specified below.

Figure 3 Widths of a Gaussian peak at various heights, as a function of the standard deviation of the peak.

3.3.06.6. *Variance of the peak* The square of the standard deviation (σ^2).

3.3.07. **Peak-widths** Peak-widths represent retention dimensions (time or volume) parallel to the baseline. If the baseline is not parallel to the axis representing time or volume, then the peak-widths are to be drawn parallel to this axis. Three peak-width values are commonly used in chromatography (see Figure 1A and Figure 3).

3.3.07.1. *Peak-width at base (w_b)* (KL in Figure 1A and Figure 3) The segment of the peak base intercepted by the tangents drawn to the inflection points on either side of the peak.

3.3.07.2. *Peak-width at half height (w_h)* (HJ in Figure 1A and Figure 3) The length of the line parallel to the peak base at 50% of the peak height that terminates at the intersection with the two limbs of the peak

Note: The peak-width at base (w_b) may be called the 'base width'. However, the peak width at half height (w_h) must never be called the 'half width' because that has a completely different meaning. Also, the symbol $w_{1/2}$ should never be used instead of w_h .

3.3.07.3. *Peak-width at inflection points (w_i)* (FG in Figure 1A and Figure 3) The length of the line drawn between the inflection points parallel to the peak base.

3.3.07.4. In the case of Gaussian (symmetrical) peaks, the peak-widths are related to the standard deviation (σ) of the peak according to the following equations:

$$w_b = 4\sigma$$

$$w_h = 2\sigma\sqrt{(2 \ln 2)} = 2.355\sigma$$

$$w_i = 2\sigma$$

3.3.08. **Tailing** Asymmetry of a peak such that, relative to the baseline, the front is steeper than the rear. In paper chromatography and thin-layer chromatography, it refers to the distortion of a spot showing a diffuse region behind the spot in the direction of flow.

3.3.09. Fronting Asymmetry of a peak such that, relative to the baseline, the front is less steep than the rear. In paper chromatography and thin-layer chromatography, it refers to the distortion of a spot, showing a diffuse region in front of the spot in the direction of flow.

3.3.10. Step The portion of an integral chromatogram recording the amount of a component, or the corresponding change in the signal from the detector as the component emerges from the column (see Figure 1B).

3.3.10.1. Step height (NM in Figure 1B) The distance, measured in the direction of detector response, between straight-line extensions of the baselines on both sides of a step.

3.3.11. Internal standard A compound added to a sample in known concentration to facilitate the qualitative identification and/or quantitative determination of the sample components.

3.3.12. External standard A compound present in a standard sample of known concentration and volume which is analysed separately from the unknown sample under identical conditions. It is used to facilitate the qualitative identification and/or quantitative determination of the sample components. The volume of the external standard (standard sample) need not to be known if it is identical to that of the unknown sample.

3.3.13. Marker A reference substance chromatographed with the sample to assist in identifying the components.

3.4. Diffusion

3.4.01. The diffusion coefficient (D) is the amount of a particular substance that diffuses across a unit area in 1 s under the influence of a gradient of one unit.

It is usually expressed in the units $\text{cm}^2 \text{s}^{-1}$.

3.4.02. Diffusion coefficient in the stationary phase (D_s or D_L) The diffusion coefficient characterizing the diffusion in the stationary phase. In partition chromatography with a liquid stationary phase, the symbol D_L may be used to express this term.

3.4.03. Diffusion coefficient in the mobile phase (D_M or D_G) The diffusion coefficient characterizing the diffusion in the mobile phase. In gas chromatography where the mobile phase is a gas, the symbol D_G may be used to express this term.

3.4.04. Diffusion velocity (u_D) This term is used in liquid chromatography in the expression of the reduced mobile-phase velocity (see 3.6.05.3). The diffusion velocity expresses the speed of diffusion into the pores of the particles:

$$u_D = D_M/d_p$$

3.5. Temperatures

3.5.01. Ambient temperature (T_a) The temperature outside the chromatographic system.

3.5.02. Injection temperature The temperature within the injection device.

3.5.03. Separation temperature (T_c) The temperature of the chromatographic bed under isothermal operation. In column chromatography it is called the *Column Temperature*.

3.5.04. Temperatures during programmed-temperature analysis

3.5.04.1. Initial temperature The temperature of the chromatographic bed (column) at the start of the analysis. Temperature programming might start immediately upon sample introduction or it can be preceded by a short isothermal period (*Initial Isothermal Temperature*). In the case, the time of the *Initial Isothermal Period* must also be specified.

3.5.04.2. *Program rate* The rate of increase of column temperature. The rate of temperature increase is usually linear ($^{\circ}\text{C}.\text{min}^{-1}$) but it may also be non-linear. During one analysis the temperature rate may be changed and/or the temperature programming may be interrupted by an isothermal period. In this case one is speaking about *Multiple Programming*. In multiple programming each program must be specified by its initial and final temperatures and program rate.

3.5.04.3. *Mid-analysis isothermal temperature* The temperature of the column in an isothermal period during elution. The corresponding time (*Mid-Analysis Isothermal Period*) must also be specified.

3.5.04.4. *Final temperature* The highest temperature to which the column is programmed.

3.5.04.5. *Final isothermal temperature* The final temperature of the program if it is followed by an isothermal period. The time corresponding to the *Final Isothermal Period* must also be specified.

3.5.04.6. *Retention temperature* The column temperature corresponding to the peak maximum.

3.5.05. **Detector temperature** The temperature of the detector cell. In the case of a detector incorporating a flame, it refers to the temperature of the detector base.

3.6. The Mobile Phase

3.6.01. **Mobile phase viscosity (η)** The viscosity of the mobile phase at the temperature of the chromatographic bed.

3.6.02. Pressures

3.6.02.1. *Inlet pressure (p_i)* The *absolute* pressure at the inlet of a chromatographic column.

3.6.02.2. *Outlet pressure (p_o)* The absolute pressure at the exit of a chromatographic column. It is usually but not necessarily equal to the *Ambient Pressure (p_a)*, the atmospheric pressure outside the chromatographic system.

3.6.02.3. *Pressure drop (Δp)* The difference between the inlet and outlet pressures:

$$\Delta p = p_i - p_o$$

3.6.02.4. *Relative pressure (P)* The ratio of the inlet and outlet pressures:

$$P = p_i/p_o$$

3.6.03. **Mobile phase compressibility correction factor (j)** A factor, applying to a homogeneously filled column of uniform diameter, that corrects for the compressibility of the mobile phase in the column. It is also called the *Compressibility Correction Factor*. In gas chromatography, the correction factor can be calculated as:

$$j = \frac{3}{2} \frac{p^2 - 1}{p^3 - 1} = \frac{3}{2} \frac{(p_i/p_o)^2 - 1}{(p_i/p_o)^3 - 1}$$

In liquid chromatography the compressibility of the mobile phase is negligible.

Note: In former nomenclatures the term 'pressure gradient correction factor' was sometimes used to express the same term. This is, however, an incorrect name, because it is not the pressure gradient but the compression of the mobile phase which necessitates the use of this factor. In liquid chromatography, where mobile phase compression is negligible, no correction factor has to be applied to the mobile phase velocity; however, there is still a pressure gradient along the column.

3.6.04. Flow rate The volume of mobile phase passing through the column in unit time.

3.6.04.1. The flow rate is usually measured at the column outlet, at ambient pressure (p_a) and temperature (T_a , in K); this value is indicated with the symbol F . If a water-containing flowmeter was used for the measurement (e.g. the so-called soap bubble flowmeter) then F must be corrected to dry gas conditions in order to obtain the *Mobile Phase Flow Rate at Ambient Temperature* (F_a):

$$F_a = F(1 - p_w/p_a)$$

where p_w is the partial pressure of water vapor at ambient temperature.

3.6.04.2. In order to specify chromatographic conditions in column chromatography, the flow-rate (*Mobile Phase Flow Rate at Column Temperature*, F_c) must be expressed at T_c (kelvin), the column temperature:

$$F_c = F_a(T_c/T_a)$$

3.6.05. Velocities

3.6.05.1. Mobile-phase velocity (u) The linear velocity of the mobile phase across the average cross-section of the chromatographic bed or column. It can be calculated from the column flow-rate at column temperature (F_c), the cross-sectional area of the column (A_c) and the interparticle porosity (ϵ):

$$u = F_c/(\epsilon A_c)$$

In practice the mobile phase velocity is usually calculated by dividing the column length (L) by the retention time of an unretained compound (t_M ; see 3.7.03):

$$u = L/t_M$$

3.6.05.2. In gas chromatography, due to the compressibility of the carrier gas, the linear velocity will be different at different longitudinal positions in the column. Therefore two terms must be distinguished:

The *Carrier Gas Velocity at the Column Outlet* (u_o) can be obtained as above, from the carrier gas flow rate measured at column outlet:

$$u_o = F_c/(\epsilon A_c)$$

The *Average Linear Carrier Gas Velocity* (\bar{u}) is obtained from u_o , by correcting it for gas compressibility:

$$\bar{u} = u_o j$$

The average linear carrier gas velocity can also be obtained by dividing the column length (L) by the retention time of an unretained compound (t_M):

$$\bar{u} = L/t_M$$

In liquid chromatography where mobile phase compression is negligible, $\bar{u} = u$.

3.6.05.3. Reduced mobile phase velocity (v) A term used mainly in liquid chromatography. It compares the mobile phase velocity with the velocity of diffusion into the pores of the particles (the so-called diffusion velocity, u_D ; see 3.4.04):

$$v = \bar{u}/u_D = \bar{u}d_p/D_M$$

In open-tubular chromatography:

$$v = \bar{u}d_c/D_M$$

3.7. Retention Parameters in Column Chromatography

3.7.01. Retention parameters may be measured in terms of chart distances or times, as well as mobile phase volumes; e.g., t'_R (time) is analogous to V'_R (volume). If recorder speed is constant, the chart distances are directly proportional to the times; similarly if the flow rate is constant, the volumes are directly proportional to the times.

Note: In gas chromatography, or in any chromatography where the mobile phase expands in the column, V_M , V_R and V'_R represent volumes under column outlet pressure. If F_c , the carrier gas flow rate at the column outlet and corrected to column temperature (see 3.6.04.2), is used in calculating the retention volumes from the retention time values, these correspond to volumes at column temperatures.

3.7.02. The various conditions under which retention volumes (times) are expressed are indicated by superscripts: thus, a prime ('; as in V'_R) refers to correction for the hold-up volume (and time) while a circle ($^\circ$; as in V_R°) refers to correction for mobile-phase compression. In the case of the net retention volume (time) both corrections should be applied: however, in order not to confuse the symbol by the use of a double superscript, a new symbol (V_N , t_N) is used for the net retention volume (time).

3.7.03. Hold-up volume (time) (V_M , t_M) The volume of the mobile phase (or the corresponding time) required to elute a component the concentration of which in the stationary phase is negligible compared to that in the mobile phase. In other words, this component is not retained at all by the stationary phase. Thus, the hold-up volume (time) is equal to the *Retention Volume (Time) of an Unretained Compound*. The hold-up volume (time) corresponds to the distance OA in Figure 1A and it includes any volumes contributed by the sample injector, the detector, and connectors.

$$t_M = V_M/F_c$$

In gas chromatography this term is also called the *Gas Hold-up Volume (Time)*.

3.7.04. Corrected gas hold-up (volume (V_M°)) The gas hold-up volume multiplied by the compression (compressibility) correction factor (j):

$$V_M^\circ = V_M \cdot j$$

Assuming that the influence of extracolumn volume on V_M is negligible,

$$V_M^\circ = V_G$$

(see 3.2.11.2)

3.7.05. Total retention volume (time) (V_R , t_R) The volume of mobile phase entering the column between sample injection and the emergence of the peak maximum of the sample component of interest (OB in Figure 1a), or the corresponding time. It includes the hold-up volume (time):

$$t_R = V_R/F_c$$

3.7.06. Peak elution volume (time) (\bar{V}_R , \bar{t}_R) The volume of mobile phase entering the column between the start of the elution and the emergence of the peak maximum, or the corresponding time. In most of the cases, this is equal to the total retention volume (time). There are, however, cases when the elution process does not start immediately at sample introduction. For example, in liquid chromatography, sometimes the column is washed with a liquid after the application of the sample to displace certain components which are of no interest and during this treatment the sample does not move along the column. In gas chromatography, there are also cases when a liquid sample is applied to the top of the column but its elution starts only after a given period. This term is useful in such cases.

3.7.07. Adjusted retention volume (time) (V'_R , t'_R) The total elution volume (time) minus the hold-up volume (time). It corresponds to the distance AB in Figure 1a:

$$V'_R = V_R - V_M$$

$$t'_R = t_R - t_M = (V_R - V_M)/F_c = V'_R/F_c$$

3.7.08. Corrected retention volume (time) (V_R° , t_R°) The total retention volume (time) multiplied by the compression correction factor (j):

$$V_R^\circ = V_R \cdot j$$

$$t_R^\circ = V_R \cdot j/F_c = V_R^\circ/F_c$$

3.7.09. Net retention volume (time) (V_N , t_N) The adjustment retention volume (time) multiplied by the compression correction factor (j):

$$V_N = V'_R \cdot j$$

$$t_N = V'_R \cdot j/F_c = V_N/F_c$$

3.7.10. In liquid chromatography, the compression of the mobile phase is negligible and thus, the compression correction factor does not apply. For this reason, the total and corrected retention volumes (times) are identical ($V_R = V_R^\circ$; $t_R = t_R^\circ$) and so are the adjusted and net retention volumes (times) ($V'_R = V_N$; $t'_R = t_N$).

3.7.11. Specific retention volumes

3.7.11.1. The specific retention volume at column temperature (V_g^θ) The net retention volume per gram of stationary phase (stationary liquid, active solid or solvent-free gel (W_s)):

$$V_g^\theta = V_N/W_s$$

3.7.11.2. Specific retention volume at 0°C (V_g) The value of V_g^θ corrected to 0°C:

$$V_g = V_g^\theta \frac{273.15 \text{ K}}{T_c} = \frac{V_N}{W_s} \frac{273.15 \text{ K}}{T_c}$$

where T_c is the column temperature (in kelvin).

3.7.12. Retention factor (k) The retention factor is a measure of the time the sample component resides in the stationary phase relative to the time it resides in the mobile phase: it expresses how much longer a sample component is retarded by the stationary phase than it would take to travel through the column with the velocity of the mobile phase. Mathematically, it is the ratio of the adjusted retention volume (time) and the hold-up volume (time):

$$k = V'_R/V_M = t'_R/t_M$$

If the distribution constant (see 3.9) is independent of sample component concentration, then the retention factor is also equal to the ratio of the amounts of a sample component in the stationary and mobile phases respectively, at equilibrium:

$$k = \frac{\text{amount of component in stationary phase}}{\text{amount of component in mobile phase}}$$

If the fraction of the sample component in the mobile phase is R (see 3.7.13), then the fraction in the stationary phase is $(1 - R)$; thus

$$k = (1 - R)/R$$

Note: In former nomenclatures and in the literature one may find the expressions *Partition Ratio*, *Capacity Ratio*, *Capacity Factor* or *Mass Distribution Ratio* to describe this term.

In the literature the symbol k' is often used for the retention factor, particularly in liquid chromatography. The original reason for this was to clearly distinguish it from the partition coefficient (distribution constant) for which the symbol K had been utilized. Since, however, the distribution constants are all identified with a subscript, there is no reason to add the prime sign to this symbol. It should be emphasized that all the recognized nomenclatures (IUPAC, BS, ASTM) have always clearly identified the capacity factor with the symbol k and not k' .

3.7.12.1. Logarithm of the retention factor This term is equivalent to the R_M value used in planar chromatography (see 3.8.05). The symbol κ is suggested to express $\log k$:

$$\kappa = \log k = \log[(1 - R)/R].$$

3.7.13. Retardation factor (R) The fraction of the sample component in the mobile phase at equilibrium; it is related to the retention factor and other fundamental chromatography terms:

$$R = 1/(k + 1)$$

3.7.14. Relative retention values

3.7.14.1. Relative retention (r) The ratio of the adjusted or net retention volume (time) or retention factor of a component relative to that of a standard, obtained under identical conditions:

$$r = V'_{Ri}/V'_{R(st)} = V_{Ni}/V_{N(st)} = t'_{Ri}/t'_{R(st)} = k_i/k_{st}$$

Depending on the relative position of the peak corresponding to the standard compound in the chromatogram, the value of r may be smaller, larger or identical to unity.

3.7.14.2. Separation factor (α) The relative retention value calculated for two adjacent peaks ($V'_{R2} > V'_{R1}$):

$$\alpha = V'_{R2}/V'_{R1} = V_{N2}/V_{N1} = t'_{R2}/t'_{R1} = k_2/k_1$$

By definition, the value of the separation factor is always greater than unity.

The separation factor is also identical to the ratio of the corresponding distribution constants.

Note: The separation factor is sometimes also called the 'selectivity'. The use of this expression is discouraged.

3.7.14.3. Unadjusted relative retention (r_G or α_G) Relative retention calculated by using the total retention volumes (times) instead of the adjusted or net retention volumes (times):

$$r_G = V_{Ri}/V_{R(st)} = t_{Ri}/t_{R(st)} = \frac{k_i + 1}{k_{st} + 1}$$

Subscript G commemorates E. Glueckauf, who first used this expression.

3.7.14.4. Relative retention (r) and separation factor (α) values must always be measured under isothermal conditions. On the other hand, the unadjusted relative retention (r_G or α_G) values may also be obtained in

programmed-temperature or gradient-elution conditions. Under such conditions, the symbol RRT (for *Relative Retention Time*) has also been used to describe the unadjusted relative retention values.

Using the same stationary and mobile phases and temperature, the relative retention and separation factor values are reproducible between chromatographic systems. On the other hand, the unadjusted relative retention (and 'relative retention time') values are only reproducible within a single chromatographic system.

3.7.15. Retention index; Kováts (retention) index (I) The retention index of a sample component is a number, obtained by interpolation (usually logarithmic), relating the adjusted retention volume (time) or the retention factor of the sample component to the adjusted retention volumes (times) of two standards eluted before and after the peak of the sample component.

In the *Kováts Index* or *Kováts Retention Index* used in gas chromatography, n -alkanes serve as the standards and logarithmic interpolation is utilized:

$$I = 100 \left[\frac{\log X_i - \log X_z}{\log X_{(z+1)} - \log X_z} + z \right]$$

where X refers to the adjusted retention volumes or times, z is the number of carbon atoms of the n -alkane eluting before, and $(z + 1)$ is the number of carbon atoms of the n -alkane eluting after the peak of interest:

$$V'_{Rz} < V'_{Ri} < V_{R(z+1)}$$

The *Kováts (Retention) Index* expresses the number of carbon atoms (multiplied by 100) of a hypothetical normal alkane which would have an adjusted retention volume (time) identical to that of the peak of interest when analyzed under identical conditions.

The *Kováts Retention Index* is always measured under isothermal conditions. In the case of *temperature-programmed gas chromatography* a similar value can be calculated utilizing direct numbers instead of their logarithm. Since both the numerator and denominator contain the difference of two values, here we can use the total retention volumes (times). Sometimes this value is called the *Linear Retention Index*:

$$I^T = 100 \left[\frac{t_{Ri}^T - t_{Rz}^T}{t_{R(z+1)}^T - t_{Rz}^T} + z \right]$$

where t_R^T refers to the total retention times (chart distances) measured under the conditions of temperature programming. The value of I^T will usually differ from the value of I measured for the same compound under isothermal conditions, using the same two phases.

3.8. Retention Parameters in Planar Chromatography

3.8.01. Mobile-phase front The leading edge of the mobile phase as it traverses the planar media. In all forms of development except radial, the mobile phase front is essentially a straight line parallel to the mobile phase surface. It is also called the *Liquid Front* or *Solvent Front*.

3.8.02. Mobile-phase distance The distance travelled by the mobile phase travelling along the medium from the starting (application) front or line to the mobile phase front. It is the distance a in Figure 2.

3.8.03. Solute distance The distance travelled by the solute along the medium from the starting (application) point or line to the center of the solute spot. If the solute spot is not circular, an imaginary circle is used whose diameter is the smallest axis of the spot. It is the distance b in Figure 2.

3.8.04. Retardation Factor (R_F) Ratio of the distance travelled by the center of the spot to the distance simultaneously travelled by the mobile phase. Using the symbols of Figure 2:

$$R_F = b/a$$

By definition the R_F values are always less than unity. They are usually given to two decimal places. In order to simplify this presentation the hR_F Values may be used: they correspond to the R_F values multiplied by 100.

Ideally, the R_F values are identical to the R values (see 3.7.13).

3.8.05. R_M value A logarithmic function of the R_F value:

$$R_M = \log \frac{1 - R_F}{R_F} = \log \left[\frac{1}{R_F} - 1 \right]$$

3.8.06. Relative retardation (R_{rel}) This term is equivalent to relative retention used in column chromatography: it is the ratio of the R_F value of a component to the R_F value of a standard (reference) substance. Since the mobile phase front is common for the two components, the R_{rel} value can be expressed directly as the ratio of the distances travelled by the spot of the compound of interest (b_i) and the reference substance (b_{st}) respectively:

$$R_{rel} = R_{F(i)}/R_{F(st)} = b_i/b_{st}$$

Note: In former nomenclatures the symbol R_s was used to express relative retardation in planar chromatography. Because of its identity with the symbol for peak resolution (see 3.10.01) the symbol R_{rel} is suggested for relative retardation in planar chromatography.

3.9. Distribution Constants

The distribution constant is the concentration of a component in or on the stationary phase divided by the concentration of the component in the mobile phase. Since in chromatography a component may be present in more than one form (e.g. associated and dissociated forms), the analytical condition used here refers to the total amount present without regard to the existence of various forms.

These terms are also called the *Distribution Coefficients*. However, the present term conforms more closely to the general usage in science.

The concentration in the mobile phase is always calculated per unit volume of the phase. Depending on the way the concentration in the stationary phase is expressed various forms of the distribution constants may exist.

3.9.01. Distribution Constant (K_c) In the general case, the concentration in the stationary phase is expressed *per unit volume of the phase*. This term is mainly applicable to partition chromatography with a liquid stationary phase but can also be used with a solid stationary phase:

$$K_c = \frac{W_{i(S)}/V_S}{W_{i(M)}/V_M}$$

where $W_{i(S)}$ and $W_{i(M)}$ are the amounts of component i in the stationary and mobile phases, while V_S and V_M are the volumes of the stationary and mobile phases, respectively.

The term *Distribution Constant* and the symbol K_c are recommended in preference to the term *Partition Coefficient* which has been in use in partition chromatography with a liquid stationary phase.

The value of K_c is related to the retention volume (V_R) of a sample component and the volumes of the stationary (V_S) and mobile phases (V_M) in the column:

$$V_R = V_M + K_c V_S$$

In gas chromatography both V_R and V_M have to be corrected for gas compressibility: therefore V_R° (see 3.7.08) is to be used for V_R , and $V_G = V_M^\circ$ (see 3.2.11.2) is to be used for V_M .

$$V_R^\circ = V_G + K_c V_S$$

3.9.02. Distribution constant (K_g) In the case of a solid stationary phase, the distribution constant may be expressed *per mass (weight) of the dry solid phase*:

$$K_g = \frac{W_{i(S)}/W_s}{W_{i(M)}/V_M}$$

where $W_{i(st)}$ and $W_{i(M)}$ are the amounts (masses) of the component i in the stationary and mobile phases, respectively, W_{st} is the mass (weight) of the dry stationary phase, and V_M is the volume of the mobile phase in the column.

3.9.03. Distribution constant (K_s) In the case of adsorption chromatography with a well characterized adsorbent of known surface area, the concentration in the stationary phase may be expressed *per unit surface area*:

$$K_s = \frac{W_{i(S)}/A_s}{W_{i(M)}/V_M}$$

where $W_{i(S)}$ and $W_{i(M)}$ are the amounts (masses) of the component i in the stationary and mobile phases, respectively, A_s is the surface area of the stationary phase, and V_M is the volume of the mobile phase in the column.

Note: The symbols used in 3.9.01 through 3.9.03 are generalized.

3.10. Terms Expressing the Efficiency of Separation

3.10.01. Peak resolution (R_s) The separation of two peaks in terms of their average peak width at base ($t_{R2} > t_{R1}$):

$$R_s = \frac{(t_{R2} - t_{R1})}{(w_{b1} + w_{b2})/2} = \frac{2(t_{R2} - t_{R1})}{w_{b1} + w_{b2}}$$

In the case of two adjacent peaks it may be assumed that $w_{b1} \approx w_{b2}$, and thus, the width of the second peak may be substituted for the average value:

$$R_s \approx (t_{R2} - t_{R1})/w_{b2}$$

3.10.02. Separation number (SN) This expresses the number of peaks which can be resolved in a given part of the chromatogram between the peaks of two consecutive n -alkanes with z and $(z + 1)$ carbon atoms in their molecules:

$$SN = \frac{t_{R(z+1)} - t_{Rz}}{w_{hz} + w_{h(z+1)}} - 1$$

In the German literature the symbol TZ (*Trennzahl*) is commonly used to express the separation number.

As the separation number depends on the n -alkanes used for the calculation, they always must be specified with any given SN value.

3.10.03. Plate number (N) A number indicative of column performance, calculated from the following equations which depend on the selection of the peak width expression (see 3.3.07):

$$N = (V_R'/\sigma)^2 = (t_R/\sigma)^2$$

$$N = 16(V_R'/w_b)^2 = 16(t_R/w_b)^2$$

$$N = 5.545(V_R'/w_h)^2 = 5.545(t_R/w_h)^2$$

The value of 5.545 stands for $8 \ln 2$ (see 3.3.07.4). These expressions assume a Gaussian (symmetrical) peak.

In these expressions the units for the quantities inside the brackets must be consistent so that their ratio is dimensionless: i.e., if the numerator is a volume, then peak width must also be expressed in terms of volume.

Note: In former nomenclatures the expressions ‘Number of Theoretical Plates’ or ‘Theoretical Plate Number’ were used for the same term. For simplification, the present name is suggested.

3.10.04. Effective plate number (N_{eff}) A number indicative of column performance calculated by using the adjusted retention volume (time) instead of the total retention volume (time). It is also called the *Number of Effective Plates*:

$$N_{\text{eff}} = (V'_R/\sigma)^2 = (t'_R/\sigma)^2$$

$$N_{\text{eff}} = 16(V'_R/w_b)^2 = 16(t'_R/w_b)^2$$

$$N_{\text{eff}} = 5.545(V'_R/w_h)^2 = 5.545(t'_R/w_h)^2$$

The plate number and effective plate number are related to each other:

$$N = N_{\text{eff}} \left[\frac{k+1}{k} \right]^2$$

Where k is the retention factor (see 3.7.12).

Notes: In the former literature the expression ‘number of effective theoretical plates’ had been used to express this term. This is incorrect since the plate number is either theoretical or effective, but cannot be both. In former nomenclatures the respective symbols n and N have been used for the plate number and the effective plate number. However, there was often a confusion in the proper selection of lower case and capital letters; therefore, the present usage, characterizing the effective plate number by a subscript, is suggested.

3.10.05. Plate height (H) The column length (L) divided by the plate number:

$$H = L/N$$

It is also called the *Height Equivalent to One Theoretical Plate* (HETP).

3.10.06. Effective plate height (H_{eff}) The column length divided by the effective plate number:

$$H_{\text{eff}} = L/N_{\text{eff}}$$

It is also called the *Height Equivalent to One Effective Plate*.

Notes: In the former literature the expression ‘height equivalent to one effective theoretical plate’ had been used to express this term. This is incorrect, since the plate height is either theoretical or effective (see 3.10.04), but cannot be both.

In former nomenclatures the respective symbols h and H have been used for the plate height and the effective plate height, respectively. However, there was often a confusion in the proper selection of lower case and capital letters and also due to the fact that h (lower case letter) is also used to express the reduced plate height (see 3.10.07). The present usage is suggested in order to avoid any confusion.

3.10.07. Reduced plate height (h) A term used in liquid chromatography. It is the ratio of the plate height to the average particle diameter:

$$h = H/d_p$$

For open-tubular columns:

$$h = H/d_c$$

4. Terms Related to Detection

4.1. Classification of Detectors

4.1.01. Classification according to the form of response

4.1.01.1. *Differential detectors* These measure the instantaneous difference in the composition of the column effluent.

4.1.01.2. *Integral detectors* These measure the accumulated quantity of sample component(s) reaching the detector.

4.1.02. Classification according to the basis of response

4.1.02.1. *Concentration-sensitive detector* A device the response of which is proportional to the concentration of a sample component in the eluent.

4.1.02.2. *Mass-flow sensitive detector* A device the response of which is proportional to the amount of sample component reaching the detector in unit time.

4.1.03. Classification according to Detector selectivity

4.1.03.1. *Universal detector* A detector which responds to every component in the column effluent except the mobile phase.

4.1.03.2. *Selective detector* A detector which responds to a related group of sample components in the column effluent.

4.1.03.3. *Specific detector* A detector which responds to a single sample component or to a limited number of components having similar chemical characteristics.

4.2. Detector Response

4.2.01. **Detector sensitivity (S)** The signal output per unit concentration or unit mass of a substance in the mobile phase entering the detector.

4.2.01.1. In the calculation of detector sensitivity the signal output of the detector is given as peak area in mV.min, A.s or AU.min (AU = absorbance unit). These values are obtained from the *integrated* peak area converted to the units specified.

Alternately, the peak area can also be obtained by multiplying the peak height at maximum (in mV, A or AU) by the peak-width at half height (in time units). The peak area calculated in this way will be 6% less than the true integrated peak area, assuming that peak is Gaussian.

4.2.01.2. In the case of *concentration-sensitive detectors*, sensitivity is calculated per unit concentration in the mobile phase:

$$S = A_i F_c / W_i = E / C_i$$

where A_i is the integrated peak area (in mV.min or AU.min), E is the peak height (in mV or AU), C_i is the concentration of the particular substance in the mobile phase at the detector (in g.cm⁻³), F_c is the mobile phase flow rate corrected to column temperature (in cm³.min⁻¹) and W_i is the mass (amount) of the substance present (in mg). The dimensions of detector sensitivity are mV.cm³.mg⁻¹ or AU.cm³.mg⁻¹.

4.2.01.3. In the case of thermal-conductivity detectors, this sensitivity value is also called the *Dimbat-Porter-Stross Sensitivity* of the detector.

In the case of *mass-flow sensitive detectors*, sensitivity is calculated per unit mass of the test substance in the mobile phase entering the detector:

$$S = A_i / W_i = E_i / M_i$$

where A_i is the integrated peak area (in A.s), E_i is the peak height (in A), M_i is the mass rate of the test substance entering the detector (in g.s⁻¹), and W_i is the mass (amount) of test substance present (in g). The dimension of detector sensitivity is A.s.g⁻¹ or C.g⁻¹.

4.2.02. Relative detector response factor (f) The relative detector response factor expresses the sensitivity of a detector relative to a standard substance. It can be expressed on an equal mole, equal volume or equal mass (weight) basis:

$$f_i = (A_i/A_{st})f_{st}$$

where A refers to the peak area of the compound of interest (subscript i) and standard (subscript st) respectively, and f_{st} is the response factor of the standard compound. Usually, an arbitrary value (e.g. 1 or 100) is assigned to f_{st} . Expressing the relative molar responses and using n -alkanes as the standards, the assigned value of f_{st} is usually the number of carbon atoms of the n -alkanes multiplied by 100 (e.g. 600 for n -hexane).

If the relative detector response factor is expressed on an equal mass (weight) basis, the determined sensitivity values can be substituted for the peak area.

4.3. Noise and Drift

4.3.01. Noise (N) (see Figure 4) The amplitude expressed in volts, amperes, or absorbance units of the envelope of the baseline which includes all random variations of the detector signal the frequency of which is in the order of one or more cycles per minute. In the case of photometric detectors the amplitude may be expressed in absorbance units per unit cell length.

4.3.02. Drift (see Figure 4) The average slope of the noise envelope, expressed in volts, amperes, or absorbance units per hour. It may be actually measured for 0.5 hour and extrapolated to one hour.

4.4. Minimum Detectability

The concentration or mass flow of a sample components in the mobile phase gives a detector signal equal to twice the noise level. It can be calculated from the measured sensitivity (S) and noise (N):

$$D = 2N/S$$

where D is the minimum detectability, expressed either as concentration or mass-flow of the substance of interest in the mobile phase at the detector. Both sensitivity and minimum detectability must be determined for the same substance.

Figure 4 Measurement of the noise and drift of a chromatographic detector.

4.5. Linear and Dynamic Ranges

4.5.01. Linear range The linear range of a chromatographic detector represents the range of concentrations or mass flows of a substance in the mobile phase at the detector over which the sensitivity of the detector is constant within a specified variation, usually ± 5 percent.

4.5.01.1. The best way to present detector linear range is the *Linearity Plot* (see Figure 5) plotting detector sensitivity against amount injected, concentration or mass flow-rate. Here, the upper limit of linearity can be graphically established as the amount, concentration, or mass flow-rate) at which the deviation exceeds the specified value ($\pm x\%$ window around the plot). The lower limit of linearity is always the minimum detectable amount determined separately for the same compound.

4.5.01.2. Alternatively, the linear range of a detector may be presented as the plot of peak area (height) against concentration or mass flow-rate of the test substance in the column effluent at the detector (see Figure 6). This plot may be either linear or log/log. The upper limit of linearity is that concentration (mass flow-rate) at which the deviation from an ideal linearity plot is greater than the specified percentage deviation ($\pm x\%$ window).

4.5.01.3. Numerically, the linear range can be expressed as the ratio of the upper limit of linearity obtained from the linearity plot and the minimum detectability, both measured for the same substance.

4.5.01.4. When presenting the linear range of a detector, either as a plot as a numerical value, the test substance, the minimum detectability, and the specified deviation must be stated.

4.5.02.

4.5.02.1. Dynamic range The dynamic range of detector is that range of concentration or mass flow-rates of a substance over which an incremental change in concentration or mass flow-rate produced an incremental change in detector signal. Figure 6 Presents a plot used for the determination of the dynamic range of a detector.

4.5.02.2. The lower limit of the dynamic range is the minimum detectability. The upper limit is the highest concentration at which a further increase in concentration (mass flow-rate) will still give an observable

Figure 5 Linearity plot of a chromatographic detector. The scale of the ordinate is linear: the scale of the abscissa may be either linear or logarithmic.

Figure 6 Determination of the linear and dynamic ranges of a chromatographic detector. Such a plot is usually in a log-log scale.

increase in detector signal, and the dynamic range is the ratio of the upper and lower limits. The dynamic range is greater than the linear range.

4.5.02.3. Numerically the dynamic range can be expressed as the ratio of the upper limit of the dynamic range obtained from the plot and the minimum detectability, both measured for the same substance.

4.5.02.4. When expressing the dynamic range of a detector, the test substance and the minimum detectability must be stated.

Table 1 Index of terms

Compound terms are generally listed at two places: under the main term and also under the full name. Exception was made when both the main term and its adjective start with same letter. For example, ion-exchange chromatography is listed as 'ion-exchange chromatography' and 'chromatography, ion-exchange'; on the other hand, column chromatography is listed only as 'chromatography, column.' The numbers refer to the relevant sections. Terms specifically used in planar chromatography (PC), ion-exchange chromatography (IEC) and exclusion chromatography (EC) are indicated by the corresponding acronyms.

A		Chamber saturation	(PC) 2.2.02.7
Active solid	3.1.01	Chromatogram	1.1.02
Adjusted retention time	3.7.07; (EC) 6.2.03	- differential	3.3.01

Porous-layer open-tubular column	3.2.03.2	- total mobile phase	(EC) 6.2.04
Post-column derivatization	1.6.11.2	- unretained compound	3.7.03; (EC) 6.2.01
Practical specific capacity	(IEC) 5.4.04	Reversed-phase chromatography	1.6.01
Pre-column derivatization	1.6.11.2		
Pressure	3.6.02	S	
- ambient	3.6.02.2	Salt form of ion exchanger	(IEC) 5.3.01.6
- drop	3.6.02.3	Sample	1.1.09
- inlet	3.6.02.1	- component	1.1.10
- outlet	3.6.02.2	- injector	2.1.02
- programming	3.6.11	Sampling valve	2.1.02.2
- relative	3.6.02.4	Selective detectors	4.1.03.2
Programmed-flow chromatography	1.6.09	Selectivity coefficient	(IEC) 5.5.02
Programmed pressure		- corrected	5.5.03
chromatography	1.6.10	Sensitivity of detectors	4.2.01
Programmed-temperature		- Dimbat-Porter-Stross	4.2.01.2
chromatography	1.6.08	Separation factor	3.7.14.2; (IEC) 5.5.04
Programmed-temperature vaporizer	2.1.02.6	Separation number	3.10.02
Program rate	3.5.04.2	Separation temperature	2.1.03
Pumps	2.1.01	Solid stationary phase	1.1.05
- pneumatic	2.1.01.3	Solid support	3.1.03
- reciprocating	2.1.01.2	Solute	1.1.11
- syringe	2.1.01.1	Solute distance	(PC) 3.8.03
Pyrolysis-gas chromatography	1.6.11.1	Solvent	1.1.12; (IEC) 5.2.01
		Sorption	(IEC) 5.1.05
		- isotherm	(IEC) 5.1.06
R		Specific capacity (IEC)	
Radial elution (development)	(PC) 2.2.02.5	- practical	5.4.04
Reaction chromatography	1.6.11	- theoretical	5.4.01
Reciprocating pump	2.1.01.2	Specific detectors	4.1.03.3
Redox ion exchanger	(IEC) 5.3.01.8	Specific permeability	3.2.18
Redox polymers	(IEC) 5.3.01.7	Specific resolution	(EC) 6.3.02
Reduced plate height	3.10.07; (EC) 6.3.05	Specific retention volume	3.7.11
Reduced velocity (of mobile phase)	3.6.05.3	Split injection	2.1.02.5
Relative pressure	3.6.02.4	Spot	(PC) 3.3.04
Relative response factor (of detector)	4.2.02	- diameter	3.3.04.1
Relative retardation	(PC) 3.8.06	Spotting device	(PC) 2.2.01

Table 1 *Continued*

Standard deviation	3.3.06.5	Theoretical plate number	3.10.03; (EC) 6.3.03
Starting point	(PC) 3.3.03	Theoretical specific capacity	(IEC) 5.4.01
Stationary mobile-phase volume	(EC) 6.1.03	Thin-layer chromatography	1.3.02
Stationary phase	1.1.05	Total mobile-phase time	(EC) 6.2.04
- volume	3.2.15	Total mobile-phase volume	(EC) 6.1.03; 6.2.04
- mass (weight)	3.2.16	Totally porous packing	3.1.07.1
Step	3.3.10	Trennzahl	3.10.02
- height	3.3.10.1	Two-dimensional chromatography	1.6.06
Stepwise elution	1.6.05		
Supercritical-fluid chromatography	1.4.04	U	
Support	3.1.03	Unadjusted relative retention	3.7.14.3
Support-coated open-tubular column	3.2.03.2	Universal detectors	4.1.03.1
Syringe pump	2.1.01.1	Unsaturated elution (development)	(PC) 2.2.02.8
T		V	
Tailing	3.3.08	Valve injector	2.1.02.2
Temperature		Variance	3.3.06.6
- ambient	3.5.01	Velocities (of mobile phase)	3.6.05.1
- column	2.1.03; 3.5.03	Viscosity (of mobile phase)	3.6.01
- detector	3.5.05	Visualization chamber	(PC) 2.2.03
- final	3.5.04.4	Void volume	3.2.11
- final isothermal	3.5.04.5	Volume capacity	(IEC) 5.4.02
- initial	3.5.04.1	Volume swelling ratio	(IEC) 5.3.06
- initial isothermal	3.5.04.1		
- injection	3.5.02	W	
- mid-analysis isothermal	3.5.04.3	Wall-coated open tubular column	3.2.03.1
- program rate	3.5.04.2	Weight-swelling ratio in solvent	(IEC) 5.3.05
- retention	3.5.04.6		
- separation	2.1.03; 3.5.03	Z	
Theoretical plate height	3.10.05; (EC) 6.3.03	Zone	1.1.13

Table 2 List of symbols

The numbers in parentheses refer to the relevant sections. Symbols used specifically in planar chromatography (PC), ion-exchange chromatography (IEC) or exclusion-chromatography (EC) are indicated by the corresponding acronyms.

<i>a</i>	Mobile phase-distance in PC (3.8.02)
<i>A</i>	Peak area (4.2.01)
<i>A_c</i>	Cross-sectional area of a column (3.2.10)
<i>A_s</i>	Surface area of stationary phase in column (3.9.03)
<i>b</i>	Solute distance in PC (3.8.03)
<i>B₀</i>	Specific permeability (3.2.18)
<i>C_i</i>	Concentration of a test substance in the mobile phase at the detector (4.2.01.2)
<i>d_c</i>	Column inside diameter (3.2.07)
<i>d_f</i>	Thickness of liquid phase film (3.2.14)
<i>d_p</i>	Particle diameter (3.1.08)
<i>D</i>	Minimum detectability of a detector (4.4)
<i>D</i>	Diffusion coefficient in general (3.4)
<i>D_{ex}</i>	Diffusion coefficient in an ion exchanger (5.5.01)
<i>D_G</i>	Diffusion coefficient in the gas phase (3.4.03)
<i>D_L</i>	Diffusion coefficient in the liquid stationary phase (3.4.02)
<i>D_M</i>	Diffusion coefficient in the mobile phase (3.4.03)
<i>D_S</i>	Diffusion coefficient in the stationary phase (3.4.02)
<i>E</i>	Peak height (4.2.01.2)
<i>f</i>	Relative detector response factor (4.2.02)
<i>F</i>	Mobile-phase flow-rate, measured at column outlet under ambient conditions with a wet flowmeter (3.6.04.1)
<i>F_a</i>	Mobile-phase flow-rate at ambient temperature (3.6.04.1)
<i>F_c</i>	Mobile-phase flow-rate, corrected to column temperature (3.6.04.2)
<i>h</i>	Reduced plate height (3.10.07)
<i>hR_F</i>	RF × 100 (3.8.04)
<i>H</i>	Plate height (height equivalent to one theoretical plate) (3.10.05)
<i>H_{eff}</i>	Effective plate height (height equivalent to one effective plate) (3.10.06; in EC: 6.3.04)

Table 2 Continued

I	Retention index; Kováts (retention) index (3.7.15)
I^T	Retention index obtained in programmed temperature analysis; Linear retention index (3.7.15)
j	Mobile phase compression (compressibility) correction factor (3.6.03)
k	Retention factor (capacity factor) (3.7.12)
k_e	Retention factor (capacity factor) in EC (6.2.05)
$k_{A,B}$	Selectivity coefficient in IEC (5.5.02)
$k_{A,B}^a$	Corrected selectivity coefficient (IEC) (5.5.03)
K	Distribution constants in general (3.9)
K_c	Distribution constant in which the concentration in the stationary phase is expressed as mass of substance per volume of the phase (3.9.01). In IEC, it refers to unit volume of the swollen ion exchanger (5.6.01)
K_g	Distribution constant in which the concentration in the stationary phase is expressed as mass of substance per mass of the solid phase (3.9.02). In IEC, it refers to unit mass of the dry ion exchanger (5.6.02)
K_s	Distribution constant in which the concentration in the stationary phase is expressed as mass of substance per surface area of the solid phase (3.9.03)
K_v	Distribution constant used in IEC, in which the concentration in the stationary phase is expressed as volume of substance per volume of the dry ion exchanger (5.6.03)
K_o	Distribution constant in EC (6.2.06)
L	Column length (3.2.09)
M	in EC: molecular mass (6.3.01 & 6.3.02)
M_i	Mass rate of the test substance entering the detector (4.2.01.3)
N	Noise of a detector (4.3.01)
N	Plate number (number of theoretical plates) (3.10.03)
N_{eff}	Effective plate number (number of effective plates) (3.10.04; in EC: 6.3.04)
p	Pressure in general (3.6.02)
p_a	Ambient pressure (3.6.02.2)
p_i	Inlet pressure (3.6.02.1)
p_o	Outlet pressure (3.6.02.2)
p_w	Partial pressure of water at ambient temperature (3.6.04.1)
Δp	Pressure drop (3.6.02.3)
P	Relative pressure (3.6.02.4)
Q_A	Practical specific capacity of an ion exchanger (5.4.04)
Q_B	Break-through capacity of an ion-exchange bed (5.4.05)
Q_V	Volume capacity of an ion exchanger (5.4.02)
r	Relative retention (3.7.14.1)
r_c	Inside column radius (3.2.08)
r_G	Unadjusted relative retention (3.7.14.3)
r_p	Pore radius (3.1.09)
R	Retardation factor in column chromatography; fraction of a sample component in the mobile phase (3.7.12 & 3.7.13)
$(R - 1)$	Fraction of a sample component in the stationary phase in column chromatography (3.7.12)
R_F	Retardation factor in PC (3.8.04)
R_M	Logarithmic function of R_F (PC) (3.8.05)
R_{rel}	Relative retardation in PC (3.8.06)
R_s	Peak resolution (3.10.01)
R_{sp}	Specific resolution in EC (6.3.02)
$R_{1/2}$	Peak resolution in EC (6.3.02)
S	Detector sensitivity (4.2.01)
SN	Separation number
t	Time in general
t_i	Retention time corresponding to the interparticle volume (V_i) of the column (EC) (6.1.02)
t_t	Retention time corresponding to the total mobile phase volume (V_t) in the column (EC) (6.2.04)
t_o	Retention time of an unretained compound in EC (6.2.01)
t_M	Mobile-phase hold-up time; except in EC (see 6.1.01) it is also equal to the retention time of an unretained compound (3.7.03)
t_N	Net retention time (3.7.09)
t_R	Total retention time (3.7.05; in EC: 6.2.02)
t_R^T	Total retention time in temperature-programmed analysis (3.7.05 & 3.7.15)
\bar{t}_R	Peak elution time (3.7.06)
t'_R	Adjusted retention time (3.7.07; in EC: 6.2.03)
t_R^c	Corrected retention time (3.7.08)
T	Temperature in general (always in kelvin) (3.5)
T_a	Ambient temperature (3.5.01)
T_c	Column temperature (3.5.03)
TZ	Trennzahl number (separation number) (3.10.02)
u	Mobile-phase velocity (3.6.05.1)

Table 2 *Continued*

\bar{u}	Average linear carrier gas velocity (3.6.05.2)
u_D	Diffusion velocity (3.4.04)
u_o	Carrier gas velocity at column outlet (3.6.05.2)
V	Volume in general
V_c	Column volume (3.2.05)
$V_{(DIE)}$	Volume of dry ion exchanger (5.6)
V_{ext}	Extra-column volume (6.1.03)
V_g	Specific retention volume at 0°C (3.7.11.2)
V_g^θ	Specific retention volume at column temperature (3.7.11.1)
V_i	Intraparticle volume of column in EC (6.1.02)
V_G	Interparticle volume of column in GC (3.2.11.2)
V_L	Liquid-phase volume (3.2.15)
V_M	Mobile-phase hold-up volume; except in EC (see 6.1.01) it is also equal to the retention volume of an unretained compound (3.7.03)
V_M^o	Corrected gas hold-up volume (3.7.04)
V_M	Volume of mobile phase in column (3.9.01)
V_N	Net retention volume (3.7.09)
V_o	Interparticle volume of column (3.2.11); in EC, it is also equal to the retention volume of an unretained compound (6.2.01)
V_R	Total retention volume (3.7.05; in EC: 6.2.02)
\bar{V}_R	Peak elution volume (3.7.06)
V'_R	Adjusted retention volume (3.7.07; in EC: 6.2.03)
V_R^o	Corrected retention volume (3.7.08)
V_S	Volume of stationary phase in column (3.2.15, 3.9.01)
$V_{(SIE)}$	Volume of swollen ion-exchanger (5.6)
$V_t^{(sol)}$	Total mobile-phase volume in the column (the mobile phase hold-up volume in EC) (6.1.03 and 6.2.04)
w_b	Peak width at base (3.3.07.1)
w_h	Peak width at half height (3.3.07.2)
w_i	Peak width at the inflection points (3.3.07.3)
W	Amount (mass) in general
W_i	Amount (mass) of a test substance present (4.2.01.2)
$W_{(IE)}$	Amount of the component i in the ion exchanger (5.6)
$W_{(M)}$	Amount of component i in the mobile phase (3.9)
$W_{(S)}$	Amount of the component i in the stationary phase (3.9)
W_L	Amount (mass) of the liquid phase in the column (3.2.16)
W_S	Amount (mass) of the stationary phase in the column (3.2.16)
z	Number of carbon atoms of a n -alkane eluted before the peak of interest (3.7.15)
$(z + 1)$	Number of carbon atoms of a n -alkane eluted after the peak of interest (3.7.15)

Greek symbols

α	Separation factor (relative retardation) (3.7.4.2)
α	Separation factor in IEC (5.5.04)
α_G	Unadjusted separation factor (relative retention) (3.7.14.3)
β	Phase ratio (3.2.17)
ε	Interparticle porosity (3.2.12)
η	Mobile phase viscosity (3.6.01)
θ	superscript in V_g^θ (3.7.11.1)
κ	$\log k$ (3.7.12.1)
ν	Reduced mobile phase velocity (3.6.05.3)
ρ	Bed density in IEC (5.6.03)
σ	Standard deviation of a Gaussian peak (3.3.06.5)
σ^2	Variance of a Gaussian peak (3.3.06.5)
Φ	Flow resistance parameter (3.2.19)

Subscripts

The generally used subscripts are listed. There are a few specific subscripts not listed here.

a	Ambient
c	Column
eff	Effective
f	Film of liquid phase
i	Compound of interest
o	Outlet of column
p	Particle
st	Standard

Table 2 *Continued**Subscripts*

G	Gas phase
L	Liquid stationary phase
M	Mobile phase; also external solution in IEC
N	Net (as in net retention time or volume; correction for both the holdup time (volume) and gas compressibility)
R	Retention (as in retention time or volume)
S	Stationary phase; in IEC: ion exchanger
1,2	Two adjacent ($t_{R2} > t_{R1}$ except in EC where $M_2 > M_1$ and thus $t_{R1} > t_{R2}$)

Superscripts

T	Indication that value was obtained in programmed-temperature analysis
'	Adjusted (as in adjusted retention time or volume)
°	Corrected (as in corrected retention time or volume)

Table 3 List of acronyms used in chromatography

EC	Exclusion chromatography
GC	Gas chromatography
GLC	Gas-liquid chromatography
GLPC	Gas-liquid partition chromatography
GPC	Gel-permeation chromatography
GSC	Gas-solid chromatography
HETP	Height equivalent to one theoretical plate
HPLC	High-performance liquid chromatography
IC	Ion chromatography
IEC	Ion-exchange chromatography
LC	Liquid chromatography
LLC	Liquid-liquid chromatography
LSC	Liquid-solid chromatography
PC	Paper chromatography or Planar chromatography
PLOT	Porous-layer open-tubular (column)
PTV	Programmed-temperature vaporizer
RRT	Relative retention time
SCOT	Support-coated open-tubular (column)
SFC	Supercritical-fluid chromatography
TLC	Thin-layer chromatography
WCOT	Wall-coated open-tubular (column)

5. Special Terminology Used in Ion-exchange Chromatography

The general terms and definitions discussed in the previous chapters are also valid in ion-exchange chromatography. In addition, the following terms and definitions refer specifically to this variant of the technique.

5.1. Basic Definitions

- 5.1.01. **Ion exchange** The process of exchanging ions between a solution and an ion exchanger.
- 5.1.02. **Counter-ions** In an ion exchanger, the mobile exchangeable ions.
- 5.1.03. **Fixed ions** In an ion exchanger, the non-exchangeable ions which have a charge opposite to that of the counter-ions.
- 5.1.04. **Ion-exchange isotherm** The concentration of a counter-ion in the ion exchanger expressed as a function of its concentration in the external solution under specified conditions and at constant temperature.
- 5.1.05. **Sorption** Uptake of electrolytes or non-electrolytes by the ion exchanger through mechanisms other than pure ion exchange.
- 5.1.06. **Sorption isotherm** The concentration of a sorbed species in the ion exchanger, expressed as a function of its concentration in the external solution under specified conditions and at constant temperature.

5.1.07. Ionogenic groups The fixed groupings in an ion exchanger which are either ionized or capable of dissociation into fixed ions and mobile counter-ions

5.1.08. Co-ions The mobile ionic species in an ion exchanger with a charge of the same sign as the fixed ions.

5.1.09. Cation exchange The process of exchanging cations between a solution and a cation exchanger.

5.1.10. Anion exchange The process of exchanging anions between a solution and an anion exchanger.

5.2. The Mobile Phase

5.2.01. Solvent The term used in classical ion exchange to express the mobile phase.

5.2.02. External solution The solution in contact with the ion exchanger which contains the ionized species before and after exchange with the ion exchanger.

5.3. The Chromatographic Medium

5.3.01. Ion exchangers A solid or liquid, inorganic or organic substance containing ions exchangeable with others of the same charge, present in a solution in which the ion exchanger is considered to be insoluble.

Note: It is recognized that there are cases where liquid exchangers are employed and where it may be difficult to distinguish between the separation process as belonging to ion exchange or liquid-liquid distribution, but the broad definition given here is regarded as that which is most appropriate.

5.3.01.1. Resin matrix The molecular network of an ion exchanger which carries the ionogenic groups.

5.3.01.2. Monofunctional ion exchanger An ion exchanger containing only one type of ionogenic group.

5.3.01.3. Bifunctional ion exchanger An ion exchanger containing two types of ionogenic groups.

5.3.01.4. Polyfunctional ion exchanger An ion exchanger containing more than one type of ionogenic groups.

5.3.01.5. Macroporous ion exchanger An ion exchanger with pores that are large compared to atomic dimensions.

5.3.01.6. Salt form of an ion exchanger The ionic form of an ion exchanger in which the counter-ions are neither hydrogen nor hydroxide ions. When only one valence is possible for the counter-ion, or its exact form or charge is not known, the symbol or the name of the counter-ion without charge is used, e.g., sodium-form or Na-form, tetramethylammonium-form, orthophosphate-form. When one of two or more possible forms is exclusively present, the oxidation state may be indicated by a Roman numeral, e.g. Fe^{II}-form, Fe^{III}-form.

5.3.01.7. Redox polymers Polymers containing functional groups which can be reversibly reduced or oxidized. *Electron Exchanger* may be used as a synonym.

5.3.01.8. Redox ion exchangers Conventional ion exchangers in which reversible redox couples have been introduced as counter-ions either by sorption or complex formation. They closely resemble redox polymers in their behavior.

5.3.02. Cation exchanger Ion exchanger with cations as counter-ions. The term *Cation-Exchange Resin* may be used in the case of solid organic polymers.

5.3.02.1. Acid form of a cation exchanger The ionic form of a cation exchanger in which the counter-ions are hydrogen ions (H-form) or the ionogenic groups have added a proton forming an undissociated acid.

5.3.03. Anion exchanger Ion exchanger with anions as counter-ions. The term *Anion-Exchange Resin* may be used in the case of solid organic polymers.

5.3.03.1. Base form of an anion exchanger The ionic form of an anion exchanger in which the counter-ions are hydroxide groups (OH-form) or the ionogenic groups form an uncharged base, e.g. $-\text{NH}_2$.

5.3.04. Ion-exchange membrane A thin sheet or film of ion-exchange material which may be used to separate ions by allowing the preferential transport of either cations (in the case of a *Cation-Exchange Membrane*) or anions (in the case of an *Anion-Exchange Membrane*). If the membrane material is made from only ion-exchanging material, it is called a *Homogeneous Ion-Exchange Membrane*. If the ion-exchange material is embedded in an inert binder, it is called a *Heterogeneous Ion-Exchange Membrane*.

5.3.04.1. Perm-selectivity A term used to define the preferential permeation of certain ionic species through ion-exchange membranes.

5.3.05. Weight-swelling ratio in solvent Mass of solvent taken up by unit mass of the dry ion exchanger. The solvent must always be specified.

5.3.06. Volume-swelling ratio Ratio of the dry swollen volume to the true dry volume of the ion exchanger.

5.4. Capacity Values

5.4.01. Theoretical specific capacity Amount (mmol) of ionogenic group per mass (g) of dry ion exchanger. If not otherwise stated, the capacity should be reported per mass (g) of the H-form of a cation exchanger and of the Cl-form of an anion exchanger.

5.4.02. Volume capacity (Q_v) Amount (mmol) of ionogenic group per volume (cm^3) of swollen ion exchanger. The ionic form of the ion exchanger and the medium should be stated.

5.4.03. Bed volume capacity Amount (mmol) of ionogenic group per bed volume (cm^3) (see 3.2.06) determined under specified conditions. The conditions should always be specified.

5.4.04. Practical specific capacity (Q_A) Total amount of ions (mmole) taken up per mass (g) of dry ion exchanger under specified conditions. The conditions should always be specified.

5.4.05. Break-through capacity of ion-exchange bed (Q_B) The practical capacity of an ion exchanger bed, obtained experimentally by passing a solution containing a particular ionic or molecular species through a column containing the ion exchanger. This is under specified conditions and is determined by measuring the amount of species which has been taken up when the species is first detected in the effluent or when the concentration in the effluent reaches some arbitrarily defined value. The break-through capacity may be expressed in millimoles or milligrams taken up per gram of dry ion exchanger or per cm^3 of bed volume.

5.5. Diffusion, Selectivity and Separation

5.5.01. Diffusion coefficient in the ion exchanger (D_{ex}) The meaning of this term is the same as the specified in 3.4.01-3.4.02.

5.5.02. Selectivity coefficient ($k_{A/B}$) The equilibrium coefficient obtained by application of the law of mass action to ion exchange and characterizing quantitatively the ability of an ion exchanger to select one of two ions present in the same solution. The ions involved in the exchange should be specified as subscripts. Examples:

Exchange: $\text{Mg}^{2+} - \text{Ca}^{2+}$

$$k_{\text{Mg/Ca}} = \frac{[\text{Mg}]_s/[\text{Ca}]_s}{[\text{Mg}]_s/[\text{Ca}]_s}$$

Exchange: $\text{SO}_4^{2+} - \text{Cl}^-$

$$k_{\text{SO}_4/\text{Cl}} = \frac{[\text{SO}_4]_S/[\text{Cl}]_S^2}{[\text{SO}_4]_M/[\text{Cl}]_M^2}$$

In the above equations subscript S refers to the ion exchanger ('stationary phase') and M to the external solution ('mobile phase'). For exchanges involving counter-ions differing in their charges, the numerical value of $k_{A/B}$ depends on the choice of the concentration scales in the ion exchanger and the external solution (molal scale, molar scale, mole fraction scale, etc.). Concentration units must be clearly stated for an exchange of ions of differing charges.

5.5.03. Corrected selectivity coefficient ($k_{A/B}^a$) This is calculated in a way identical to the selectivity coefficient except that the concentrations in the external solutions are replaced by activities.

5.5.04. Separation factor ($\alpha_{A/B}$) The definition of this term is identical to the definition given in 3.7.14.2. In an exchange of counter-ions of equal charge the separation factor is equal to the selectivity coefficient (see 5.5.01), provided that only one type of ion represents the analytical concentration (e.g. in exchanges of K^+ and Na^+) but not in systems where several individual species are included in the analytical concentrations.

5.6. Distribution constants

A *Distribution Constant* is the concentration of a component in the ion exchanger (the stationary phase) divided by its concentration in the external solution (the mobile phase). The concentration in the external solution is always calculated per unit volume. Depending on the way the concentration in the ion exchanger is expressed three forms of the distribution constant may exist.

In 5.6.01-5.6.03, $W_{i(\text{IE})}$ and $W_{i(\text{sol})}$ are the amounts of the component i in the ion exchanger and in the external solution; V_{SIE} and V_{DIE} are the volumes of the swollen and dry ion exchanger, respectively; $V_{(\text{sol})}$ is the volume of the external solution.

5.6.01. Distribution constant (K_c) In this case, the concentration in the ion exchanger is calculated as mass (weight)/volume and it refers to the swollen ion exchanger:

$$K_c = \frac{W_{i(\text{IE})}/V_{(\text{SIE})}}{W_{i(\text{sol})}/V_{(\text{sol})}}$$

5.6.02. Distribution constant (K_g) In this case, the concentration in the ion exchanger is calculated as mass/mass (weight/weight) and it refers to dry ion exchanger:

$$K_g = \frac{W_{i(\text{IE})}/V_{(\text{DIE})}}{W_{i(\text{sol})}/V_{(\text{sol})}}$$

5.6.03. Distribution constant (K_v) In this case, the concentration in the ion exchanger is calculated as volume/volume and it refers to the dry ion exchanger:

$$K_v = \frac{V_{i(\text{IE})}/V_{(\text{DIE})}}{W_{i(\text{sol})}/V_{(\text{sol})}}$$

If the *Bed Density* is ρ , expressed in grams of dry resin per cm^3 of bed, then

$$K_v = K_g \rho$$

6. Special Terminology Used in Exclusion Chromatography

Besides the terms and definitions used in general in chromatography, a number of special terms exist in exclusion chromatography. In addition, due to the different nature of the chromatographic separation, some

Figure 7 Retention characteristics in exclusion chromatography. A standard sample is analysed (top); subsequently, the retention volumes (times) are plotted against the logarithms of the corresponding molecular weights. Peak A corresponds to a non-retained sample component the molecules of which are larger than the largest pores in the gel particles (total exclusion); peak D corresponds to a sample component the molecules of which are smaller than the smallest pores in the gel particles (total penetration).

of the general chromatographic terms have a different meaning here. For further explanation of some of the terms, see Figure 7.

Below, only the *chromatography* terms are listed. For a discussion of the molecular weight terms calculated from the chromatographic data see the specialized nomenclatures (e.g. refs. 15–18).

6.1. The Column

6.1.01. Interparticle volume of the column (V_0) The volume of the mobile phase in the interstices between the gel particles. It is also called the *Interstitial Volume* of the column.

In exclusion chromatography, the interparticle volume of the column is equal to the retention volume of an unretained compound; however, it is *not* equal to the mobile phase hold-up volume (V_t). The reason for this is that in practice the mobile phase molecules are always smaller than the smallest pores of the column packing. Thus, they will enter all the pores available in the packing and therefore, will be eluted last. As a contrast, in general liquid chromatography, the mobile-phase hold-up volume (see 3.7.03) and the retention volume of a non-retained compound are practically equal.

6.1.02. Intraparticle volume of the column (V_i) The volume of the mobile phase within the pores of the gel particles. It is also called the *Intrastitial Volume* of the column or the *Stationary Mobile-Phase Volume*.

The retention time equivalent to V_i is t_i :

$$t_i = V_i / F_c$$

6.1.03. Total mobile-phase volume in column (V_t) The sum of the interparticle and intraparticle volumes:

$$V_t = V_0 + V_i$$

In the definition of V_t the extra-column volume of the system (V_{ext} ; see 3.2.13) is neglected. If it is not negligible, it must also be added:

$$V_t = V_0 + V_i + V_{ext}$$

6.2. Retention Parameters

6.2.01. Retention volume (time) of an unretained compound (V_o , t_o) The retention volume of a sample component the molecules of which are larger than the largest pores of the gel particles. These will be eluted first from the column. The corresponding retention time is t_o :

$$t_o = V_o/F_c$$

Ignoring any extra-column volume, V_o is equal to the interparticle volume of the column (see 6.1.01).

6.2.02. Retention volume (time) (V_R , t_R) The retention volume (time) of a sample component the molecules of which are smaller than the largest pores of the gel particles but larger than the smallest pores. The corresponding retention time is t_R :

$$t_R = V_R/F_c$$

6.2.03. Adjusted retention volume (time) (V'_R , t'_R) The total retention volume less the retention volume of an unretained compound:

$$V'_R = V_R - V_o$$

The corresponding retention time is t'_R :

$$t'_R = t_R - t_o = V'_R/F_c = (V_R - V_o)/F_c$$

6.2.04. Total mobile phase volume (time) (V_t , t_t) The retention volume (time) of a sample component the molecules of which are smaller than the smallest pores of the gel particles. The corresponding retention times is t_t :

$$t_t = V_t/F_c$$

6.2.05. Retention factor (k_e) The ratio of the adjusted retention volume (time) and the retention volume (time) of an unretained compound:

$$k_e = \frac{V_R - V_o}{V_o} = \frac{t_R - t_o}{t_o}$$

It may also be called the *Capacity Factor*. However, the suggested expression better defines its real meaning (see also 3.7.12).

6.2.06. Distribution constant in exclusion chromatography (K_o) The fraction of the intraparticle volume (the volume of the pores) available to the molecules of a particular sample component for diffusion:

$$K_o = \frac{V_R - V_o}{V_i}$$

For an unretained compound, $V_R = V_o$ and thus, $K_o = 0$. On the other hand, for a compound the molecules of which are smaller than the smallest pores, $V_R = V_t$ and thus, $K_o = 1$. In other words, the value of K_o varies between zero and unity.

In exclusion chromatography, K_o is related to the retention volume of a sample component and the inter- and intraparticle volumes of the column (V_o and V_i , respectively) in a manner analogous to the relationship in general liquid chromatography:

$$V_R = V_o + K_o V_i$$

6.3. Efficiency Terms

6.3.01. Peak resolution ($R_{1/2}$) The definition of this term is identical to that given in 3.10.01.

$$R_{1/2} = \frac{V_{R1} - V_{R2}}{(w_{b1} + w_{b2})/2}$$

Here V_{R1} and V_{R2} represent the peaks corresponding to compounds with molecular masses M_1 and M_2 respectively: by definition $M_2 > M_1$. In exclusion chromatography, larger molecules are eluted first, therefore, $V_{R1} > V_{R2}$.

Because of the addition of a new term, the specific resolution (see 6.3.02), the symbol $R_{1/2}$ is suggested for peak resolution in exclusion chromatography.

6.3.02. Specific resolution (R_{sp}) Peak resolution also considering the molecular masses of the two test compounds:

$$R_{sp} = \frac{V_{R1} - V_{R2}}{(w_{b1} + w_{b2})/2} \frac{1}{\log(M_2/M_1)}$$

The test compounds used for the determination of the specific resolution should have a narrow molecular-mass distribution (the ratio of the mass-average and number-average molecular masses should be equal to or less than about 1.1) and differ by a factor of about 10 in their molecular masses.

Note: In some nomenclatures, the symbol R_s is used for the specific resolution. Due to the possibility of confusing it with the general resolution term (see 3.10.01), the symbol R_{sp} is suggested here.

6.3.03. Plate number and plate height (N, H) The definitions of these terms are identical to those given in 3.10.03 and 3.10.05.

6.3.04. Effective plate number and effective plate height (N_{eff}, H_{eff}) The definitions of these terms are identical to those given in 3.10.04 and 3.10.06, except that the retention volume of a non-retained compound (V_o ; see 6.2.01) is used in the calculations:

$$N_{eff} = 16 \left[\frac{V_R - V_o}{w_b} \right]^2 = 5.545 \left[\frac{(V_R - V_o)}{w_h} \right]^2$$

$$N_{eff} = 16 \left[\frac{t_R - t_o}{w_b} \right]^2 = 5.545 \left[\frac{(t_R - t_o)}{w_h} \right]^2$$

$$H_{eff} = L/N_{eff}$$

6.3.05. Reduced plate height (h) The definition of this term is identical to that given in 3.10.07.

12B. Liquid-Liquid Distribution (Solvent Extraction) (IUPAC Recommendations 1993)

Prepared for publication by

N. M. Rice, H. M. N. H. Irving (1980) and M. A. Leonard* (1987)

*The Queens University of Belfast, Belfast, UK

© 1993 IUPAC

Abstract

The widespread use of liquid-liquid distribution, ranging from an analytical chemical technique to a unit operation in various fields of chemical technology (e.g. petroleum refining, nuclear fuel reprocessing, hydrometallurgy, food technology, biochemistry) has led to a proliferation of terminology. This paper extends the scope of the definitions beyond those previously recommended (*Pure Appl. Chem.* 1970, **21**, 111–113) and a list of terms, including those previously published, is presented under the following general headings: general definitions of phenomena, operations and relationships; components of the solvent phase; fundamental parameters for quantitative description of liquid-liquid distribution systems; process terminology applicable to large scale continuous operations.

Introduction

In 1970 IUPAC published 'Recommended Nomenclature for Liquid-Liquid Distribution' [1] which represented the work of several generations of the Nomenclature Commission V.3 of the International Union of Pure and Applied Chemistry, assisted by the work of an *ad hoc* working party which considered the whole of the nomenclature of separation processes. The choice of terms selected for definition was somewhat arbitrarily restricted to those commonly used in what might be termed small scale batch or laboratory analytical procedures. Many requests were received to extend the range of terms defined and the need for a complete revision was emphasized by the publication independently of other nomenclature proposals [2–5].

The wide variation [6] in the choice of symbols and in nomenclature adopted by authors of papers published in the Proceedings of the International Conferences on Solvent Extraction in Gothenburg (1966) and in Scheveningen (1971) convinced the organizing committee of the next conference at Lyons (ISEC-1974) of the desirability of providing authors with an extensive set of recommendations in order to aim at consistency in nomenclature and symbols in the published proceedings. These were drawn up by a working party of the Solvent Extraction and Ion Exchange Group of the Society of Chemical Industry (SCI), after meetings at Bradford and Birmingham (England) attended by representatives of all aspects of the field. Their report, drawn up by Dr Rice (as Secretary) formed the basis of discussions at the IUPAC General Assembly held in Munich during August 1973. This led to a new set of recommendations which were made available for comment at ISEC-74. After further discussions at a meeting of Commission V.3 of IUPAC in London in November 1974 and at the IUPAC General Assembly in Madrid in 1975, a tentative document was issued as an Information Bulletin [7] by IUPAC in July 1977 and further discussed at the IUPAC General Assembly in Warsaw in August 1977. At almost the same time the Solvent Extraction and Ion Exchange Group of the SCI authorized publication of their considered proposals for Recommended Nomenclature for Solvent Extraction in *Chemistry in Industry* to coincide with the International Solvent Extraction Conference (ISEC-77) in Toronto [8]. A synthesis of all these proposals including the comments received on the tentative IUPAC proposals was discussed at the IUPAC General Assembly in Davos in September 1979, and circulated in draft form at ISEC-80 in Liege in September 1980, where some minor amendments to process terminology were proposed. Further discussion took place at Commission meetings in London in December 1980 and Leuven in September 1981.

These revised recommendations have been drawn up in collaboration with the Committee of the Solvent Extraction and Ion Exchange Group of the Society of Chemical Industry and have been discussed at several International Solvent Extraction Conferences.

Following the rearrangement of Commissions at the 35th IUPAC General Assembly in Lund in 1989, this project became the responsibility of the Limited Life Time Commission on Chromatography and Other Analytical Separations.

Since automated methods of analysis frequently simulate many of the features of large-scale industrial practice – not least in that the attainment of distribution equilibrium or quantitative extraction is not always achieved or even necessary – it seemed important in revising the original nomenclature to increase the scope of the terms previously defined so as to provide chemical engineers, clinical biochemists, food technologists, hydrometallurgists, nuclear technologists, petrochemists and physical as well as analytical chemists with a comprehensive set of symbols and nomenclature. In order to distinguish what might be termed 'processing' nomenclature, from that of a more fundamental nature, the recommendations have been placed in separate sections. However, the importance of achieving consistent usage and a common language for all users of

liquid-liquid extraction cannot be overstressed. The distinction between the two sets of terms is merely one of convenience and does not imply any real difference in their importance. In many instances, it is difficult to decide the appropriate category for a certain term so that the classification is somewhat arbitrary. Furthermore, some additional terms commonly used in the metallurgical industry have been added since publication of the tentative proposals [7].

In order to keep the definitions as general as possible the liquid phases involved have been designated as 'extract' or 'solvent' rather than 'organic phase' and 'other phase' or 'feed' rather than 'aqueous phase'. The need clearly to label and specify the relevant phase in any equations or graphs is emphasized. Symbols are recommended for a few of the more important parameters. The clear designation of the extract phase components is stressed; the term 'solvent' should be reserved for the composite phase rather than any individual component although it may be the only component in that phase. Terms which have become jargon in particular industrial situations or which may be confusing because of ambiguity have been listed as "not recommended". No attempt has been made to define standard chemical engineering terms, e.g. mass transfer coefficient, but certain terms, e.g. 'equilibrium constant' are discussed in relation to their usage in liquid-liquid distribution.

When the nomenclature is applied to other types of extraction systems (e.g. two immiscible aqueous phases, such as a concentrated salt solution and a concentrated aqueous solution of poly(ethylene glycol), two immiscible non-aqueous liquids or two immiscible molten salts), the two immiscible phases should be clearly specified and can equally well be distinguished and denoted by the general terms, Phase I and Phase II. It is also recognized that in the petrochemical and food-processing industries the extractant phase may well be an inorganic liquid (e.g. liquid sulfur dioxide, supercritical carbon dioxide). This situation can be described by using the terms "epi-phase" and "hypo-phase" for the less dense and more dense phases, respectively, recognizing that mass transfer could be in either direction. Occasionally, cases arise where metals are partitioned among three liquid phases, such as concentrated KCl, acetonitrile and hexane. The application of the recommended nomenclature to any situation is clearly a matter of common sense. What is important is that in a given situation the phases used should be completely specified.

Since the 'organic phase' is commonly quite a complex solution of one or more organic liquids containing one or more extractants and possibly 'modifiers' of various sorts as well as a 'diluent', particular care has been taken over the definitions applicable to these various components.

'Concentration' is frequently used in the list of definitions. In general any suitable concentration units may be employed but the *same* units should be used for each phase and should be clearly specified in the text.

Following normal convention, 'activities' rather than 'concentrations' should be used where thermodynamic equilibrium quantities are implied. However, use of the appropriate 'concentration quotient' as an approximation for the equilibrium constant in the limiting case of dilute solutions or in conjunction with the appropriate activity coefficients follows logically.

One semantic problem is the occurrence of three English terms – 'extraction', 'distribution' and 'partition' – to describe the transfer of a solute between phases whereas in many other languages only one suitable term exists (e.g. Verteilung). An attempt has been made to obviate this difficulty in the present work but its complete avoidance is not possible owing to established usage. The terms and symbols, which have been defined are listed in Tables 1 and 2, respectively. In some cases these represent changes, clarifications, or specific usages of previously defined terms [9], in particular those related to chromatographic separations [10], and the differences are not in Appendix 1.

The current reviser (MAL) suggests use of the term 'distribution' when referring to the total concentration of related species and 'partition' when referring to a single species. The term 'constant' should be reserved for fixed thermodynamic true constants, otherwise 'ratio' should be used. A survey of the literature shows reasonable agreement over the symbol and title of *partition constant* and *distribution ratio* but nomenclature for the *partition ratio* is a nightmare. Appendix 2 summarizes past usage.

1. General Definitions

1.1 Antagonism

The converse to *synergism* (1.23).

Note: The terms *anti-synergism*, *antisynergic* and *anti-synergistic* should not be used.

1.2 Coextraction

Formation of mixed-species aggregates in a low-polarity organic phase.

1.3 Conditioning

A synonym for *pre-equilibration* (1.16).

1.4 Distribution

The apportionment of a solute between two phases.

Note: the term *partition* (1.15) or *extraction* (1.9) may also be used in this sense where appropriate.

1.5 Distribution Isotherm

The relationship (algebraic or graphical) between the concentration of a solute in the *extract* (2.7) and the corresponding concentration of the same solute in the other phase at equilibrium at a specified temperature.

Note: Alternative terms in common use are *equilibrium line* (1.7) and in the appropriate contexts: *extraction isotherm*, *scrubbing isotherm* and *stripping isotherm*. *Partition isotherm* is not normal usage.

1.6 Equilibration

The operation by which a system of two or more phases is brought to a condition where further changes with time do not occur.

Note: This term is not synonymous with *pre-equilibration* (1.16) and should not be used in that sense.

1.7 Equilibrium Line

A plot of the distribution isotherm (1.5).

1.8 Extract (Verb)

To transfer a solute from a liquid phase to another immiscible or partially miscible liquid phase in contact with it.

Notes:

- (i) The term is also applied to the dissolution of material from a solid phase with a liquid in which it is not wholly soluble (i.e. *leaching*). See *solvent extraction* (1.19).
- (ii) For usage as a noun see under '2 Components of the Solvent Phase'.

1.9 Extraction (in Liquid-liquid Distribution)

See *liquid-liquid extraction*.

Notes:

- (i) See under '4 Process Terminology' for a more specific usage of *extraction*.
- (ii) *Distribution* (1.4) and *partition* (1.15) are often used as synonyms for the general phenomenon of *extraction* where appropriate.

1.10 Liquid Ion Exchange

A term used to describe a liquid-liquid extraction process that involves a transfer of ionic species from the extractant to the aqueous phase in exchange for ions from the aqueous phase.

Notes:

- (i) The term does not imply anything concerning the nature of the bonding in the extracted complex.
- (ii) The term "*Solvent Ion Exchange*" (SIX) is not recommended.

1.11 Liquid-liquid Distribution (Extraction) (Partition)

The process of transferring a dissolved substance from one liquid phase to another (immiscible or partially miscible) liquid phase in contact with it.

Note: Although *extraction*, *partition* and *distribution* are not synonymous, *extraction* may replace *distribution* where appropriate.

1.12 Macro-element See *Main Solute*.

Notes:

- (i) This term is vague and is not recommended.
- (ii) Macroelement has a different meaning in analytical chemistry and the term *major component*, the meaning of which is obvious, is preferable.

1.13 Main (extractable) solute.

That (or those) species transferred which is of greatest economic or chemical interest.

Note: It is not necessarily the species present at greatest concentration.

1.14 Micro-element

This term should *not* be used in the sense of a minor component or a *contaminant* in the feed to a liquid-liquid distribution system.

Note: Microelement has a different meaning in analytical chemistry and the terms *minor component*, *impurity* or *contaminant* the meaning of which are obvious, are preferable.

1.15 Partition

This term is often used as a synonym for *distribution* (1.4) and *extraction* (1.9). However, an essential difference exists by definition between *distribution constant* or *partition ratio* (3.17) and *partition constant* (3.16).

Note: This term should be, but is not invariably, applied to the distribution of a single definite chemical species between the two phases.

1.16 Pre-equilibration

- (i) Preliminary treatment of a solvent in order to convert the extractants into a suitable chemical form.
- (ii) Preliminary treatment of either phase with a suitable solution of the other phase (in the absence of *main extractable solute(s)* (1.13)) so that when the subsequent *equilibration* (1.6)) is carried out changes in the (volume) *phase ratio* (3.19) or in the concentrations of other components are minimised.

Notes:

- (i) The use of *equilibration* (1.6) in this sense is confusing and should be avoided.
- (ii) The term *conditioning* may be used as a synonym for *pre-equilibration*.

1.17 Re-extraction

Since the prefix 're-' can signify 'back' as well as 'again' this term is ambiguous and *should be avoided*, except where the process of extraction (e.g. from aqueous solution to an organic phase) in a single direction is repeated (following stripping). It should not be used as a synonym for *stripping* (4.3) or *back-extraction* (4.1).

1.18 Salting Out

The addition of particular electrolytes to an aqueous phase in order to increase the *distribution ratio* (3.5) of a particular solute.

Notes:

- (i) The addition of electrolytes to improve phase separation behaviour should not be referred to as salting out.
- (ii) The term is also used for the addition of electrolytes to reduce the mutual partial miscibility of two liquids.
- (iii) It has no connection with *synergism* (1.23).

1.19 Solvent Extraction

The process of transferring a substance from any matrix to an appropriate liquid phase. If the substance is initially present as a solute in an immiscible liquid phase the process is synonymous with *liquid-liquid extraction* (1.11).

Notes:

- (i) If the extractable material is present in a solid (such as a crushed mineral or an ore) the term *leaching* may be more appropriate. The extractable material may also be a liquid entrapped within or adsorbed on a solid phase.
- (ii) Common usage has established this term as a synonym for *liquid-liquid distribution* (1.11). This is acceptable provided that no danger of confusion with extraction from solid phases exists in a given context.

1.20 Solvent Ion Exchange (SIX)

This term is not recommended (see *liquid ion exchange*) (1.10).

1.21 Sublation

A flotation process in which the material of interest, adsorbed on the surface of gas bubbles in a liquid, is collected on an upper layer of immiscible liquid.

Notes: There is no liquid-phase mixing in the bulk of the system; as a result recoveries can approach 100%.

1.22 Substoichiometric Extraction

Here the amount of reagent used is lower than that dictated by stoichiometry. If the constants of formation and extraction of the complexes are high, the amount of extracted metal is dictated by the amount of extractant introduced.

1.23 Synergism

A term describing the co-operative effect of two (or more) *extractants* (2.8) where the *distribution ratio* (3.5) for the combination is greater than the largest individual *distribution ratio* (measured under comparable conditions)

Notes:

- (i) The corresponding adjective is *synergic* and the term *synergistic* should not be used.
- (ii) No standard method for quantification of the phenomenon has been agreed and any approach should be clearly defined in a given situation.

2. Components of the Solvent Phase

2.1 Accelerator See *Catalyst* (2.3), *Kinetic Synergist* (2.10), *Modifier* (2.11)

Note: This term may be used as a synonym for catalyst.

2.2 Carrier See *Diluent* (2.5)

This term is not recommended.

2.3 Catalyst (in Liquid-liquid Distribution)

A substance included in the *solvent* (2.12) to increase the rate of transfer without affecting the position of equilibrium.

Notes: The term *accelerator* may also be used but *kinetic synergist* is not recommended.

2.4 Cosolvent See *Diluent* (2.5)

2.5 Diluent

The liquid or homogeneous mixture of liquids in which *extractant(s)* (2.8) and possible *modifier(s)* (2.11) may be dissolved to form the *solvent* (2.12) phase.

Notes:

- (i) The term *carrier*, which implied an inert diluent is not recommended.
- (ii) Although the diluent may well be a single liquid or even the major portion of the extracting phase, the term *solvent* (2.12) should not be used in this sense as it has a much wider meaning in the context of liquid-liquid extraction, although the term *cosolvent* may be used in certain circumstances.
- (iii) The diluent by itself does not extract the *main (extractable) solute* appreciably

2.6 Epi-Phase

The less dense phase in a distribution system.

Note: The term is often used when two non-aqueous phases are present or when the *solvent* (2.12) is an aqueous solution. See also *hypo-phase* (2.9).

2.7 Extract (Noun)

The separated phase (often but not necessarily organic) that contains the material extracted from the other phase.

Notes:

- (i) Where appropriate the term “*loaded solvent*” (4.15) may be used, but is not recommended.
- (ii) For usage as a verb see 1.8.

2.8 Extractant

The active component(s) primarily responsible for transfer of a solute from one phase to the other.

Notes:

- (i) The term *extracting agent* is a synonym but *solvent* (2.12) and *ligand* should not be used in this context.
- (ii) Certain *extractants* that consist of liquids immiscible with water (e.g. Tributyl phosphate or certain ketones) might comprise the only component of the initial organic phase but *extractant(s)* can also be dissolved in *diluent* (2.5).

2.9 Hypo-Phase

The denser phase in an extraction system.

Note: The term is often used when two non-aqueous phases are present or when the *solvent* (2.12) is an aqueous phase. See also *epi-phase* (2.6).

2.10 Kinetic Synergist

This term is not recommended as a synonym for *catalyst* (2.3) or *accelerator* (2.1).

2.11 Modifier

A substance added to a *solvent* (2.12) to improve its properties e.g. by increasing the solubility of an *extractant* (2.8), changing interfacial parameters, or reducing adsorption losses.

Note: Additives used to enhance extraction rates should be called *accelerators* (2.1) or *catalysts* (2.3).

2.12 Solvent (in Liquid-liquid Distribution)

The term applied to the whole initial liquid phase containing the *extractant* (2.8).

Notes:

- (i) The solvent may contain only *extractant* or it may be a composite homogeneous mixture of *extractant(s)* (2.8) with *diluent(s)* (2.5) and also sometimes *modifiers* (2.11) and *accelerators* (2.1).
- (ii) The term *solvent* must not be used as a synonym for any of the individual components of a composite liquid phase even where, in the case of a single component (e.g. 3-methylbutan-2-one or tributyl phosphate), it becomes identical with the *extractant*.
- (iii) The term may be qualified to denote the *extract* from a given processing *step* (4.41), e.g. *loaded solvent* (4.15).

3. Fundamental Parameters

3.1 Concentration Factor

Not recommended. See *extraction factor* (3.10).

3.2 Decontamination Factor

The ratio of the proportion of contaminant to product before treatment to the proportion after treatment. It is the reciprocal of the *enrichment factor* (3.6).

3.3 Distribution Coefficient

This term is not recommended as a synonym for *distribution ratio* (3.5).

3.4 Distribution Constant

A synonym for *partition ratio* (3.17).

3.5 Distribution Ratio (in Liquid-liquid Distribution) (*D*)

The ratio of the total analytical concentration of a solute in the *extract* (2.7) (regardless of its chemical form) to its total analytical concentration in the other phase.

Notes:

- (i) If there is possible confusion with the *extraction factor* or (*mass*) *distribution ratio* (3.13), the term *concentration distribution ratio* (symbol D_C) should be used, but this is not common usage. This is reasonably compatible with chromatographic nomenclature.
- (ii) The terms *distribution coefficient*, *extraction coefficient* and, where appropriate, *scrubbing coefficient*, *stripping coefficient* are widely used alternatives but are not recommended. If they must be used in a given situation the term *ratio* is preferable to *coefficient*.
- (iii) In equations relating to aqueous/organic systems the organic phase concentration is, by convention, the numerator and the aqueous phase concentration the denominator. In the case of *stripping ratio* the opposite convention is sometimes used but should then be clearly specified.
- (iv) In the past there has been much confusion between the *distribution ratio* as defined above, the value of which varies with experimental conditions, e.g. pH, presence of complexing agents, extent of achievement of equilibrium, etc. and the true *partition constant* (3.16) which is by definition invariable or the *partition coefficient* or *distribution constant* which apply to a particular chemical species under specified conditions. For this reason the terms *distribution constant* (3.4), *partition constant* (3.16), *partition coefficient* (3.15), *partition ratio* (3.17) and *extraction constant* (3.9) should not be used in this context.
- (v) The use of the ratio: *light phase concentration to heavy phase concentration* is ambiguous and is not recommended.
- (vi) The *distribution ratio* is an experimental parameter and its value does not necessarily imply that distribution equilibrium between the phases has been achieved.

3.6 Enrichment Factor (in Liquid-liquid Distribution) (*S*)

The factor by which the ratio of the amounts of two substances in the *feed* (4.11) must be multiplied to give their ratio after treatment.

$Q_A/Q_B = S_{A,B}(Q'_A/Q'_B)$ where Q_A and Q'_A are the final and initial amounts of species A and Q_B and Q'_B are the final initial amounts of species B. Hence $S_{A,B} = E_A/E_B$ where E is the *fraction extracted* (3.11). In terms of D , n , r (where n is the number of stages and r the *phase ratio* (3.19))

$$S_{A,B} = \frac{1 - (1 + rD_A)^{-n}}{1 - (1 + rD_B)^{-n}}$$

3.7 Extractability

A property which qualitatively indicates the degree to which a substance is extracted.

Note: This term is imprecise and generally used in a qualitative sense. It is not a synonym for *fraction extracted* (3.11).

3.8 Extraction Coefficient

This term is not recommended as a synonym for *distribution ratio* (3.5).

3.9 Extraction (Equilibrium) Constant at Zero Ionic Strength (K_{ex}°)

The equilibrium constant of the distribution reaction expressed in terms of the reacting species. Thus, for the gross reaction:

in which the reagent HL initially dissolved in an organic phase reacts with a metal ion M^{n+} in aqueous solution to form a product ML_n which is more soluble in the organic phase than in water,

$$K_{\text{ex}}^{\circ} = \frac{a_{\text{ML}_n,\text{org}} \times a_{\text{H}^{+},\text{aq}}^n}{a_{M^{n+},\text{aq}} \times a_{\text{HL},\text{org}}^n}$$

Notes:

- (i) When concentrations are used instead of activities or mixed terms are employed as when H^{+} and/or M^{n+} are measured with an electrode, the appropriate name is *extraction constant*, symbol K_{ex} , accompanied by a careful definition. K_{ex}° may be termed the *thermodynamic extraction constant*.
- (ii) The extraction constant is related to other terms relevant to such systems by:

$$K_{\text{ex}} = \frac{D_{\text{ML}_n} \beta_n K_a^n}{D_{\text{HL}}^n}$$

where β_n is the overall formation constant of ML_n and K_a is the dissociation constant of HL. When the reagent HL is more soluble in water than the other immiscible phase it may be more convenient to define a special equilibrium constant in terms of HL_{aq} :

$$K_{\text{ex}} = D_{\text{ML}_n} \beta_n K_a^n$$

- (iii) In distribution equilibria involving non-aqueous systems, e.g. liquid SO_2 , molten salts and metals, the mass action equilibrium constant for the relevant extraction process can be identified with K_{ex} which should be explicitly defined in this context.
- (iv) In actual practice, it may be necessary to include other terms to take into account other complexes formed by auxiliary reagents and the solvation and/or polymerization of the various species. In such cases, K_{ex} must be defined with reference to the relevant explicit chemical equation. An example is complex formation between the metal ion and an uncharged crown ether or cryptand molecule followed by ion-pair extraction:

$$K_{\text{ex}} = \frac{[\text{ML}^{n+} A_n^{n-}]_{\text{org}}}{[M^{n+}]_{\text{aq}} [L]_{\text{org}} [A^{-}]_{\text{aq}}^n}$$

- (v) Use of Ringbom's "conditional extraction constant",

$$K_{\text{ex}}^{\text{eff}} = \frac{a_{\text{H}^{+}}^n \cdot [\text{ML}'_n]_{\text{org}}}{[M']_{\text{aq}} [\text{HL}'_n]_{\text{org}}^n}$$

in conjunction with alpha coefficients is useful [11].

- (vi) The phases can also be specified by the formula of the solvent or by other symbols (preferably Roman numerals) or by overlining formulae referring to one phase, usually the less polar one. The subscript aq (or w) is often omitted; aq is preferable to w as the latter is appropriate only in English and German.
- (vii) The qualification "Equilibrium" is often omitted.
- (viii) The terms *partition constant* and *distribution constant* **must not** be used in this sense.

3.10 Extraction Factor (D_m)

The ratio of the total mass of a solute in the extract to that in the other phase.

Notes:

- (i) It is the product of the (*concentration*) *distribution ratio* and the appropriate *phase ratio*.
- (ii) It is synonymous with the *concentration factor* or *mass distribution ratio*, this latter term being particularly apt.
- (iii) The term *concentration factor* is often employed for the overall *extraction factor* in a process or process step.

3.11 Fraction Extracted (E)

The fraction of the total quantity of a substance extracted (usually by the solvent) under specified conditions, i.e. $E_A = Q_A/Q'_A$ where Q_A is the mass of A extracted and Q'_A is the total mass of A present at the start.

Notes:

- (i) E may be expressed as a percentage, % E .
- (ii) The term *extractability* is qualitative and should not be used as a synonym for *fraction extracted*.
- (iii) If the aqueous phase is extracted with n successive portions of solvent, the phase volume ratio (solvent/feed) being r each time, the fraction extracted is given by:

$$E_n = 1 - (rD + 1)^{-n}$$

If $n = r = 1$, $E_1 = D/(1 + D)$ this expression is a concept of value in chromatography theory.

- (iv) The fraction extracted is also known as the *recovery factor*, especially for a multistage process.

3.12 Loading Capacity

The maximum concentration of solute(s) that a *solvent* (2.12) can contain under specified conditions.

Notes:

- (i) The terms *maximum loading*, *saturation capacity* and *saturation loading* are synonymous.
- (ii) All the above terms should clearly be distinguished from *ultimate capacity* (3.29)

3.13 Mass Distribution Ratio See Extraction Factor (3.10)**3.14 Maximum Loading See Loading Capacity (3.12)****3.15 Partition Coefficient**

This term is not recommended and should not be used as a synonym for *partition constant* (3.16), *partition ratio* or *distribution ratio* (3.5).

3.16 Partition Constant (K_D°)

The ratio of activity of a given species A in the extract to its activity in the other phase with which it is in equilibrium, thus

$$(K_D^\circ)_A = a_{A,org}/a_{A,aq}$$

Its value should not vary with composition but depends on the choice of standard states and on the temperature (and eventually the pressure).

Note: See *transfer activity coefficient* (3.28).

3.17 Partition Ratio (K_D)

The ratio of the concentration of a substance in a single definite form, A, in the *extract* (4.8) to its concentration in the same form in the other phase at equilibrium, e.g. for an aqueous/organic system

$$(K_D)_A = [A]_{org}/[A]_{aq}$$

Notes:

- (i) K_D is sometimes called the *distribution constant*; this is a good synonym. The terms *distribution coefficient*, *distribution ratio* (3.5), *partition constant* (3.16) and *extraction constant* (3.9) should not be used as synonyms for *partition ratio*.
- (ii) The use of the inverse ratio (aqueous/organic) may be appropriate in certain cases, e.g. where the organic phase forms the *feed* (4.11) but its use in such cases should be clearly specified. The ratio of the concentration in the denser phase to the less dense phase is not recommended as it can be ambiguous.
- (iii) If the pure *solvent* and infinitely dilute feed are taken as the standard state, $K_D \rightarrow K_D^\circ$ as the total concentration of dissolved materials decreases.

3.18 $pH_{0.5}$ or $pH_{1/2}$

That value of pH in an aqueous phase at which the *distribution ratio* (3.5) is unity at equilibrium.

Note: 50% of the solute is extracted ($E = 0.5$) *only* when the *phase ratio* (3.19) is unity.

3.19 Phase Ratio (in Liquid-liquid Distribution) (r)

The ratio of the quantity of the solvent (2.12) to that of the other phase.

Notes:

- (i) Unless otherwise specified the phase ratio refers to the *phase volume ratio*.
- (ii) If other aspects of the phase ratio are employed viz. *phase mass ratio*, *phase flow ratio*, these should be specified.

3.20 Recovery Factor

This term is not recommended. *Fraction extracted* (3.11) should be used.

3.21 Saturation Capacity See *Loading Capacity* (3.12)

3.22 Saturation Loading See *Loading Capacity* (3.12)

3.23 Selectivity Coefficient

This term should not be used as a synonym for *separation factor* (3.26).

Note: This term has a specific meaning in relation to ion exchange by solid exchangers.

3.24 Selectivity Ratio

Synonym for *selectivity coefficient* (3.23). It should not be used as a synonym for *separation factor* (3.26).

3.25 Separation Coefficient

This term is not recommended. A synonym for *separation factor* (3.26).

3.26 Separation Factor (in Liquid-liquid Distribution) ($\alpha_{A,B}$)

The ratio of the respective *distribution ratios* (3.5) of two extractable solutes measured under the same conditions.

$$\alpha_{A,B} = D_A/D_B$$

Notes:

- (i) By convention the solutes designated as A and B in the above are chosen so as to make $\alpha > 1$.
- (ii) The term *separation coefficient* is not recommended.
- (iii) The terms *selectivity coefficient* (3.23) and *selectivity ratio* (3.24) are not synonymous and should not be used.

3.27 Stoichiometric Capacity See *Ultimate Capacity* (3.29)**3.28 Transfer Activity Coefficient (γ_t)**

A term used to quantify the difference in the free energy of a solute ion in two different standard states often in two different liquid phases. The relationship is $\Delta_t G^\circ = v RT \ln \gamma_t$ where $\Delta_t G^\circ$ is the transfer Gibbs energy and v is the number of ions in the solute. See *partition constant*.

Notes:

- (i) See *IUPAC Information Bulletin* No. 34 (1974) [12] for full details.
- (ii) It should not be confused with the *mass transfer coefficient* which represents the specific rate of transfer of a species from one phase to another.
- (iii) It does not necessarily imply the physical transfer of a solute between two liquid phases.

3.29 Ultimate Capacity

The theoretical maximum capacity of a *solvent* (2.12) containing a given concentration of *extractant* (2.8) for a solute under any conditions.

Note: Where appropriate the term *stoichiometric capacity* can be used.

4. Process Terminology**4.1 Back Extraction**

A synonym for *stripping* (by extraction) (4.43).

4.2 Back Washing

Often used as a synonym for *stripping* (4.43). This term is not recommended.

4.3 Continuity Inversion

A change in the mutual dispersion of two phases in contact. See *inversion* (4.13).

4.4 Crowding

The displacement of an impurity from an extract phase by contact with a solution containing the main extractable solute. See *scrubbing* (4.23), *exchange extraction* (4.8).

Note: The main solute need not be present in a pure solution but should have a higher *distribution ratio* (3.5) than the impurities present.

4.5 Crud

A deposit or emulsion at the interface between two partially settled phases.

Notes:

- (i) The phenomenon of crud formation arises from many causes and this definition does not imply any single one.
- (ii) Other terms – some unprintable – have been used but *crud* is the generally accepted term.

4.6 Density Inversion

The interchange of the denser and less dense phases due to changes in solute concentration. See *inversion* (4.13).

Note: *Phase inversion* (4.20) is often used in this context but is ambiguous.

4.7 Differential Contactor

A type of continuous multistage extraction equipment in which there is only one interface at which phase separation by settling occurs. See *theoretical stage* (4.52).

4.8 Exchange Extraction

An extraction operation or process in which a metal from one phase is exchanged with the equivalent amount of a second metal from the other phase. See *crowding* (4.4).

Note:

- (i) This term may be used in connection with any step (e.g. *loading*, (4.16), *scrubbing* (4.23) or *stripping* (4.43) in a process).
- (ii) This applies also to organic or molecular species.

4.9 Extraction (in Process Liquid-liquid Distribution)

In connection with processes, this term often refers to the initial transfer step whereby the *main solute* (1.13), often together with impurities, is transferred from *feed* to *solvent* (2.12). See *loading* (4.16).

Notes:

- (i) *Partition and distribution* (1.4) are not synonyms in this specific instance.
- (ii) The term *extraction* may be used in a more general sense. See under “General Definitions” (1.9).

4.10 Extraction Isotherm See Distribution Isotherm (1.5)**4.11 Feed**

A solution introduced into an *extraction* system.

Note: It should be clearly identified (e.g. *scrub feed*) but, if used without qualification, it may be taken to designate the initial liquid phase containing the main solute to be transferred.

4.12 Height Equivalent to a Theoretical Stage (HETS)

See explanation of *Theoretical Stage* (4.52).

4.13 Inversion (or Phase Inversion)

This term is used in two senses which should be specified.

- (i) *density inversion* (4.6)
- (ii) *continuity inversion* (4.3)

4.14 Load (in Liquid-liquid Distribution) (Verb)

To transfer solute from a *feed* (4.11) to another liquid phase.

4.15 Loaded Solvent See Extract (2.7)

Note: This term is usually used to denote the *extract* (2.7) after completion of a particular step, e.g. *extraction* or *scrubbing* (4.23)

4.16 Loading (Noun)

The concentration of an extracted solute in the *extract* (2.7).

4.17 Loading (Verb) See Load (4.14)

Note: Used in this sense the term normally refers to the operation of transferring the *main solute* (1.13)), often with impurities from the *feed* to the *solvent* (2.12).

4.18 O.K. Liquor

Sometimes used as a synonym for *strip product solution* (4.48) or *strip liquor* (4.42)

Note: This term is confusing and **should not** be used.

4.19 Operating Line

A graphical representation of the mass balance relationship of a solute across an extraction process *step* (4.41) or *stage* (4.38).

4.20 Phase Inversion See *Density Inversion* (4.6)**4.21 Raffinate**

The phase remaining after extraction of some specified solute(s). *When necessary* it should be further specified, e.g. *scrub raffinate* (4.30).

Note: The original meaning of *raffinate* as a “refined product” has become extended and changed by common usage.

The term should normally be applied only to waste streams but the latter may form the feed to a further extraction process for another solute.

4.22 Regeneration See *Solvent Regeneration* (4.37)**4.23 Scrubbing See *Crowding* (4.2) and *Selective Stripping* (4.33)**

The process of selectively removing contaminating solutes (impurities) from an *extract* (2.7) that contains these as well as the *main extractable solute* (1.13) by treatment with a new immiscible liquid phase.

Note: The term *stripping* (4.43) has a different meaning and should not be used in this sense although this usage has been customary in certain industries.

4.24 Scrubbing Agent

The chemical reagent used to effect *scrubbing* (4.23).

Note: Often used as a synonym for its solution.

4.25 Scrubbing Agent Solution

The solution used to effect *scrubbing* (4.23)

Note: The term *scrub solution* is ambiguous and is not recommended.

4.26 Scrubbing Isotherm See *Distribution Isotherm* (1.5)**4.27 Scrub Feed**

The *extract* (2.7) to be scrubbed.

4.28 Scrub Liquor See *Scrub Raffinate* (4.30)

Note: This term is ambiguous and is not recommended.

4.29 Scrub Product Solution

The solution that results from the *scrubbing* of impurities from an extract phase.

Note: The term *scrub liquor* is also used but can be confused with the *scrubbing agent solution* (4.25) and is not recommended. See *scrub raffinate* (4.30).

4.30 Scrub Raffinate

This term should only be used where the product solution from scrubbing is discharged to waste. *Scrub product solution* (4.29) is better where this stream is combined with *feed* (4.11) to the loading section.

4.31 Scrubbing Ratio See *Distribution Ratio* (3.5)

Note: The term *scrubbing coefficient* is not recommended. This term is not common.

4.32 Scrub Solution See *Scrubbing Agent Solution* (4.25)

Note: This term should not be used as it is ambiguous and can be confused with *scrub raffinate* (4.30) or *scrub product solution* (4.29).

4.33 Selective Scrubbing See *stripping* (4.43)**4.34 Solvent Inventory**

The total quantity of solvent present in the process.

4.35 Solvent Loss

The total quantity of solvent lost during the operation of a process.

Note: There are a number of ways currently in use to express both *solvent inventory* and *solvent loss* and authors should carefully define how they are using the terms until a generally agreed procedure can be recommended.

4.36 Solvent Purification

See *solvent regeneration*. The description *solvent purification* naturally applies also to the purification of fresh solvent (2.12).

4.37 Solvent Regeneration

Treatment of the solvent for re-cycling, e.g. by removal of degradation products or non-strippable solutes.

Note: The term *solvent purification* is synonymous, but the terms *scrubbing* (4.23), *stripping* (4.31) and *washing* should not be used in this context.

4.38 Stage

That physically distinct part of an extraction process in which transfer of solute(s) occurs, followed by phase separation. See *theoretical stage* (4.52).

Notes:

- (i) For certain types of equipment with a single phase separation interface, the term *theoretical stage* (4.52) is more appropriate.
- (ii) Equilibrium need not necessarily be established in a stage.

4.39 Stagewise Contactor

A type of continuous multi-stage liquid-liquid contactor in which each stage has a physically distinct cycle of interphase contact and separation.

Note: There will be the same number of phase separation interfaces as there are stages.

4.40 Steady State (in Liquid-liquid Distribution)

The state of a continuous process when it is operating in such a way that the concentration of solutes in exit streams remains constants with respect to time for constant feed concentrations, even though the two phases are not necessarily in thermodynamic equilibrium in any part of the process.

Note: The term *equilibrium* should not be used to describe this situation.

4.41 Step (in Liquid-liquid Distribution)

That operation in an overall extraction process in which transfer of solute(s) occurs in a particular direction, e.g. *Loading* (4.16), *stripping* (4.43), *scrubbing* (4.23).

4.42 Strip Liquor

A liquid phase resulting from the operation of *stripping* (4.43). See *strip solution* (4.50) and *strip raffinate* (4.49).

Notes:

- (i) This term is ambiguous and should be used carefully. *Strip raffinate* (4.49) is more appropriate.
- (ii) The term O.K. *Liquor* (4.18) is not recommended.

4.43 Stripping

The process of removing solute(s) from a *loaded solvent* or *extract* (2.7). Generally this refers to the main solute(s) present.

Notes:

- (i) Where appropriate, e.g. when liquid-liquid distribution is used for *stripping*, the term *back-extraction* can be used. The terms *back-washing* and *re-extraction* (1.17) are not recommended.
- (ii) The recent application of *selective stripping* of solutes as a separation method leads to some confusion between the terms *stripping* and *scrubbing* (4.23). It is recommended that the term *scrubbing* be reserved for the operation of removing contaminants (impurities) from an *extract* (2.7) (where the *scrub raffinate* (4.30) is often recycled to the loading step) and the term *selective stripping* be used where two or more main solutes are stripped successively from an *extract*, usually with different *stripping agents* (4.44), with a view to their subsequent separate recovery from solution for analysis.

4.44 Stripping Agent

The active substance effective in *stripping* (4.43).

4.45 Stripping Agent Solution

The liquid phase used to accomplish *stripping* (4.43).

4.46 Stripping Ratio See *Distribution Ratio* (3.5)

Notes:

- (i) This term is usually defined as the inverse ratio to the *distribution ratio* (3.5, comment iii), i.e. in aqueous-organic systems the aqueous phase concentration of solute is the numerator and the organic phase concentration the denominator. Their usage should be clearly defined.
- (ii) The term *stripping coefficient* is not recommended.

4.47 Stripping Ratio See *Distribution Isotherm* (1.5), *Equilibrium Line* (1.7)

Note: In the graphical representation of *stripping isotherms*, the axes are often interchanged from those used to represent the phases for *extraction isotherms*. It is essential that the axes be clearly labelled.

4.48 Strip Product Solution

The liquid phase resulting from *stripping* (4.43) of a *solvent* (2.12). See *stripping liquor* (4.42), *strip solution* (4.50), *strip raffinate* (4.30), *O.K. liquor* (4.18).

Note: The last four terms are not recommended.

4.49 Strip Raffinate

This term is not recommended. *Raffinate* (4.21) should be reserved for waste streams and the liquid phase resulting from stripping normally contains the desired product.

4.50 Strip Solution

The liquid phase used for *stripping* (4.43).

Note: There is some ambiguity between the terms *strip liquor* and *strip solution*. Perhaps *strip product solution* (4.48) would be more appropriate to the former and *stripping agent solution* (4.45) for the latter. See *stripping agent* (4.44).

4.51 Tenor

A term sometimes used to denote the concentration levels of various solutes in the *feed* (4.11). It is not recommended.

4.52 Theoretical Stage

That part of a continuous multi-stage contactor in which the amount of solute transferred from one phase to the other is equivalent to that which would be transferred in an actual stage at equilibrium under comparable conditions of solute concentration in each phase as determined from the *distribution isotherm* (1.5) and *operating line* (4.19) for the system.

Note: Thus from the number of theoretical stages so determined and the height of the contactor the *height equivalent to a theoretical stage* (HETS) may be calculated.

4.53 Washing See solvent regeneration (4.37)

Note: This term is vague and is not recommended.

Table 1 Index of terms

Accelerator	2.1	Partition coefficient	3.15
Antagonism	1.1	Partition constant	3.16
Back extraction	4.1	Partition ratio	3.17
Back washing	4.2	pH _{0.5} or pH _{1/2}	3.18
Carrier	2.2	Phase inversion	4.13, 4.20
Catalyst (in liquid-liquid distribution)	2.3	Phase ratio (in liquid-liquid distribution)	3.19
Coextraction	1.2	Pre-equilibration	1.16
Concentration factor	3.1	Raffinate	4.21
Conditioning	1.3	Regeneration	4.22
Continuity inversion	4.3	Recovery factor	3.20
Cosolvent	2.4	Re-extraction	1.17
Crowding	4.4	Salting out	1.18
Crud	4.5	Saturation capacity	3.21
Decontamination factor	3.2	Saturation loading	3.22
Density inversion	4.6	Scrubbing	4.23
Differential contactor	4.7	Scrubbing agent	4.24
Diluent	2.5	Scrubbing agent solution	4.25
Distribution	1.4	Scrubbing isotherm	4.26
Distribution coefficient	3.3	Scrub feed	4.27
Distribution constant	3.4	Scrub liquor	4.28
Distribution isotherm	1.5	Scrub product solution	4.29
Distribution ratio (in liquid-liquid distribution)	3.5	Scrub raffinate	4.30
Enrichment factor (in liquid-liquid distribution)	3.6	Scrubbing ratio	4.31
Epi-phase	2.6	Scrub solution	4.32
Equilibration	1.6	Selectivity coefficient	3.23
Equilibrium line	1.7	Selectivity ratio	3.24
Exchange extraction	4.8	Selective stripping	4.33
Extract (noun)	2.7	Separation coefficient	3.25
Extract (verb)	1.8	Separation factor (in liquid-liquid distribution)	3.26
Extractability	3.7	Solvent	2.12
Extractant	2.8	Solvent extraction	1.19
Extraction	1.9	Solvent inventory	4.34
Extraction (in process liquid-liquid distribution)	4.9	Solvent ion exchange (six)	1.20
Extraction coefficient	3.8	Solvent loss	4.35
Extraction factor	3.10	Solvent purification	4.36
Extraction isotherm	4.10	Solvent regeneration	4.37
Feed	4.11	Stage	4.38
Fraction extracted	3.11	Stagewise contactor	4.39
Height equivalent to a theoretical stage (HETS)	4.12	Steady state (in liquid-liquid distribution)	4.40
Hypo-phase	2.9	Step (in liquid-liquid distribution)	4.41
Inversion	4.13	Stoichiometric capacity	3.27
Kinetic synergist	2.10	Strip liquor	4.42
Liquid ion exchange	1.10	Stripping	4.43
Liquid-liquid distribution (extraction) (partition)	1.11	Stripping agent	4.44
Load (in liquid-liquid distribution) (verb)	4.14	Stripping agent solution	4.45
Loaded solvent	4.15	Stripping ratio	4.46
Loading (noun)	4.16	Stripping isotherm	4.47
Loading (verb)	4.17	Strip product solution	4.48
Loading capacity	3.12	Strip raffinate	4.49
Macro-element	1.12	Strip solution	4.50
Main (extractable) solute	1.13	Sublation	1.21
Mass distribution ratio	3.13	Substoichiometric extraction	1.22
Maximum loading	3.14	Synergism	1.23
Micro-element	1.14	Tenor	4.51
Modifier	2.11	Theoretical stage	4.52
O.K. Liquor	4.18	Transfer activity coefficient	3.28
Operating line	4.19	Ultimate capacity	3.29
Partition	1.15	Washing	4.53

Table 2 Index of symbols

D	Distribution ratio (in liquid-liquid distribution)	3.5
S	Enrichment factor (in liquid-liquid distribution)	3.6
D_m	Extraction factor	3.10
K_{ex}^o	Extraction (equilibrium) constant at zero ionic strength	3.9
E	Fraction extracted	3.11
K_d^o	Partition constant	3.16
K_d	Partition ratio	3.17
r	Phase ratio (in liquid-liquid distribution)	3.19
$\alpha_{A,B}$	Separation factor (in liquid-liquid distribution)	3.26
γ_t	Transfer activity coefficient	3.28

Appendix 1. Comparison of Nomenclature With Previously Defined Terms

(OB, Orange Book [9]; Chrom, Nomenclature for Chromatography [10])

Carrier (2.12) This term is not recommended in this area (OB p54)

Catalyst (in liquid-liquid distribution) (2.3) Defined as a specific use of *catalyst* (OB p56).

Diluent (2.5) Redefined from OB 9.2.4 and 9.2.10 in a more general sense

Distribution (1.4) Now defined – only mentioned in OB 9.2.6

Distribution coefficient (3.3) Not recommended in this area (OB 9.4.10)

Distribution constant (3.4) Matches uses in Chrom 3.9 and 5.6.

Distribution ratio (in liquid-liquid distribution) (3.5) Slight clarification of usage from OB 9.2.6

Enrichment factor (in liquid-liquid distribution) (3.6) Rewording of OB 9.2.8 to make more general.

Extractant (2.8) Redefined compared to OB 9.2.11

Extraction (in liquid-liquid distribution) (1.9) See more precise term OB 9.2.4

Extraction coefficient (3.8) Not recommended (OB 9.2.6)

Extraction constant (3.9) Slightly amended from OB 9.2.5

Liquid-liquid distribution (1.11) Redefined from OB 9.2.4

Mass distribution ratio (3.13) Unchanged from OB 9.4.10. Not recommended in Chrom 3.7.12.

Modifier (2.11) Term now defined (see OB 9.2.4)

Partition (1.15) Term now defined (OB 9.2.1)

Partition coefficient (3.15) and *partition constant* (3.16) Not recommended (OB 9.2.6) agrees 3.9.01

Recovery factor (3.20) Now not recommended (OB 9.2.7)

Salting out (1.18) Definition broadened from OB 9.2.15

Selectivity coefficient (3.23) Not recommended in this area (used in Chrom 5.5.02)

Separation factor (in liquid-liquid distribution) (3.25) Specifically defined for this area to distinguish from Chrom 3.7.14.2 and 5.5.04

Solvent (in liquid-liquid distribution) (2.12) Specific definition provided for this area more limited than OB 9.1.2 and redefines 9.2.9. Differs from Chrom 1.1.11 and 5.2.01

Appendix 2. Survey of Partition Terminology Used by Authors of Books

Term: Activities of a single species $\frac{a_{A,org}}{a_{A,aq}}$

Symbol	Name	Reference
K_D°	Partition constant	9
P°	Activity partition constant	13
P	Partition coefficient or Distribution coefficient	14, 15
K_p	Thermodynamic partition constant	16
p° or K_p°	Thermodynamic partition constant	17
P	Thermodynamic partition coefficient or Partition coefficient	18
K_D	Distribution coefficient	19
K	Distribution coefficient	15

Term: Total concentration of related species $\frac{(C_A)_{org}}{(C_A)_{aq}}$

Symbol	Name	Reference
D_c	Concentration distribution ratio	9, 16, 31
D	Distribution ratio	14, 19, 20, 22, 23, 25, 26, 27, 31, 33, 34, 37
D	Distribution coefficient	17, 18, 37, 38
D^{Total}	Distribution coefficient	34
q	Distribution coefficient	11
Q	Extraction coefficient	39
E	Extraction coefficient	36
E	Distribution ratio	17, 35

Term: Concentration distribution of $\frac{[A]_{org}}{[A]_{aq}}$ a single species

Symbol	Name	Reference
K_D	Distribution constant	9, 20, 21
K_D	Distribution coefficient	21, 22, 23, 24
K_D	Distribution or partition coefficient	25
K_D	Partition coefficient	26
K_D	Partition constant	27
K	Partition coefficient	14, 28, 29
K or λ	Partition ratio	30
K	Partition or Distribution coefficient	31
K	Distribution coefficient	15
K_p	Partition coefficient	16
P	Partition constant or coefficient	32
P	Partition coefficient or distribution constant	33
P	Partition ratio	17, 18
D	Distribution ratio	11, 34
Q	Partition ratio	35
Q_c	Molar partition constant	36

Term: Equilibrium constant for:

$$\text{i.e.} = \frac{[ML_n]_{org} \times [H^+]_{aq}^n}{[M]_{aq}^n \times [HL]_{org}^n}$$

Symbol	Name	Reference
K_{ex}°	Extraction constant at zero ionic strength (activities in above)	9
K_{ex}	Extraction constant or Overall extraction constant	9, 19, 20
K_{ext}	Extraction equilibrium constant	32
K	Extraction constant	39
K'_{ex}	Conditional extraction constant	11

12C. Non-Linear Chromatography (IUPAC Recommendations 1996)

Prepared for publication by

J. Å. Jönsson, University of Lund, Lund, Sweden

© 1996 IUPAC

Synopsis

This report summarizes and comments on terms and symbols used for the description of non-linear chromatography.

Introduction

In the IUPAC recommendations *Nomenclature for Chromatography* [1], the conditions of linear chromatography are tacitly assumed. In all versions of chromatography, however, non-linear effects are common. These are seen as concentration-dependent retention times and asymmetric (e.g. tailing or fronting) peaks. Asymmetric peaks can result from a number of other causes as well, i.e. large extra-column volumes. In many applications, non-linear effects are disadvantageous as they decrease peak resolution and disturb quantitative evaluation. However, in preparative chromatography, heavy overloading is employed in order to increase material throughput, leading to prominent non-linear effects. A comprehensive text on non-linear chromatography has recently been published [2].

In this paper, some of the concepts and terms used for non-linear chromatography are described. It is to read as a complement to the *Nomenclature for Chromatography* (CN) [1], to which numerous references are given.

1. Terms Related to Isotherms

1.1 Distribution Isotherm (in Chromatography)

The equilibrium relation between the concentration of a sample component in the stationary phase c_s , and in the mobile phase c_M , expressed as a function $c_s = f(c_M)$.

Note: The relation can be influenced also by concentrations of other sample components. c_s and c_M are usually expressed *per unit volume of the phase*; c_s may also be expressed *per mass of the dry solid phase* or *per unit surface area*. This is discussed in CN, section 3.9.

In some versions of chromatography, a distribution isotherm can be seen as a *partition isotherm*, an *adsorption isotherm*, or a combination of these, depending on the mechanism of separation (cf. CN 1.5).

1.1.1 Partition isotherm (in chromatography) Isotherm describing partition of the sample component between the bulk of a liquid stationary phase and a liquid, gaseous or supercritical mobile phase.

1.1.2 Adsorption isotherm Isotherm describing adsorption of the sample component on the surface of the stationary phase from the mobile phase.

Note: Adsorption isotherms can be described by Langmuir, Freundlich and other adsorption isotherm equations. See [3], p. 13.

1.2 Linear Distribution Isotherm

A distribution isotherm which can be approximated as $c_s = K_C c_M$, where K_C is a constant.

Note: At low concentrations, all distribution isotherms tend towards being linear. K_C is the *distribution constant* (cf. CN 3.9 and 3.4 in ref. 4).

1.3 Non-linear Distribution Isotherm

A distribution isotherm which is not linear.

Note: A non-linear isotherm can have several shapes, as classified by Brunauer *et al.* [5]. In chromatography convex or concave shapes are common, as well as combinations.

1.3.1 Convex isotherm Distribution isotherm, the slope of which is continuously decreasing (see Figure 1A).

Figure 1 Different types of distribution isotherms for the concentrations of a compound in the stationary (C_s) and mobile (C_M) phases: (A) convex isotherm, (B) concave isotherm.

Note: The resulting chromatographic peak is tailing (CN 3.3.08). Adsorption isotherms are often of this type. A special case is the Langmuir adsorption isotherm.

1.3.2 Concave isotherm Distribution isotherm, the slope of which is continuously increasing (see Figure 1B).

Note: The resulting chromatographic peak is fronting (CN 3.3.09). In gas-liquid chromatography, overloading often results in a concave isotherm.

2. Types of Chromatographic Processes

2.1 Linear Chromatography

Chromatographic process, where the retention is governed by a linear distribution isotherm.

2.2 Non-linear Chromatography

Chromatographic process, where the retention is governed by a non-linear distribution isotherm.

2.3 Ideal Chromatography

Chromatographic process, where no peak-broadening effects (such as diffusion, slow mass transfer, etc.) operate.

Note: This is a hypothetical case, implying that the plate number (CN 3.10.03) is infinite.

2.4 Non-ideal Chromatography

Chromatographic process with normal peak-broadening effects.

2.5 Non-ideal, Linear Chromatography

Chromatographic process, where the retention is governed by a linear distribution isotherm and normal peak-broadening take place.

Note: This case is commonly assumed in analytical chromatography, as described in ref. 1.

2.6 Ideal, Non-linear Chromatography

Chromatographic process, where only the curvature of the distribution isotherm determines the shape of the peaks while other peak-broadening processes are neglected.

Note: The assumption of ideal, non-linear (INL) chromatography is often made in order to facilitate theoretical treatments. It can be justified in cases of efficient columns and distribution isotherms with prominent non-linearity.

2.7 Non-ideal, Non-linear Chromatography

Chromatographic process, where both isotherm curvature and other peak-broadening processes (such as diffusion) contribute to the peak shape.

Note: This case comprises most peaks in common practice that are characterized as ‘tailing’ or ‘fronting’.

3. Retention Parameters in Non-Linear Chromatography

3.1 Total Retention Volume (Time) in Ideal, Non-linear Chromatography ($V_{R(INL)}$, $t_{R(INL)}$)

The volume of mobile phase entering the column between sample introduction and the emergence of a certain concentration of the sample component at the column outlet; or the corresponding time.

Note: This volume (time) can be measured to the peak maximum or to other points on the peak. Under the conditions of ideal, non-linear chromatography, the total retention volume is given by:

$$V_{R(INL)} = V_M + \frac{\partial c_s}{\partial c_M} \cdot V_s \quad (1)$$

With a constant flow rate F_c through the column, the *total retention time in ideal, non-linear chromatography* is given by $t_{R(INL)} = V_{R(INL)}/F_c$ as in CN 37.05. If appropriate, V_s in equation (1) may be exchanged for the surface area of the stationary phase or the mass of the stationary phase, depending on the definition of c_s (cf. 1.1 and CN 3.9). In the case of a linear distribution isotherm, equation (1) is in agreement with corresponding equation in CN 3.9.01. Note that the retention is determined by the *slope* of the isotherm, not by the *ratio* c_s/c_M . This particular point was discussed by Helfferich [6].

Typical peaks in ideal, non-linear chromatography are shown in **Figure 2**. The curved (‘diffuse’) flanks are described by equation (1) and the area of the peak (determined by the total amount of the sample component) gives the position of the vertical flank.

The retention volume in ideal, non-linear chromatography is thus a function of the mobile phase concentration of the sample component. The retention volume to the maximum of the peak (cf. CN 3.7.05) is related the value of the slope of the distribution isotherm at the maximum value of the mobile phase concentration of the sample component at the column outlet.

The broadening of the peaks in Figure 2 is totally caused by the isotherm non-linearity. As the derivation of equation (1) implies that the plate number N is infinite, it is obviously meaningless to apply equations such as those described in CN 3.10.03 and 3.10.04 to characterize peaks of this kind.

3.2 Total Retention Volume (Time) in Non-ideal, Non-linear Chromatography ($V_{R(NINL)}$, $t_{R(NINL)}$)

The definition is analogous to that in 3.1 above.

Figure 2 Typical peak shapes in ideal, non-linear chromatography. Peaks A and B are generated by equation (1) from the distribution isotherms in Figures 1A and 1B, respectively. The numbers 1, 2, 4 signify the relative amounts of the sample component. The retention time at low sample concentration, i.e. in the case that the curvature of the distribution isotherm is negligible, is indicated with an arrow.

Note: In the general case of non-ideal, non-linear (NINL) chromatography, only numerical solutions to the applicable non-linear partial differential equations involved can be found. Several examples are found ref 2, where simulated NINL peaks are compared with INL peaks with the same parameters, except for the diffusion term. It is seen that the NINL peaks are lower, wider and more tailing than the INL peak. With a reasonably efficient column ($N > 5000$ for symmetric peaks), the difference might be neglected for practical purposes.

Thus, even if no explicit equation for the retention volume in the NINL case can be given, Equation (1) is approximately valid also for a NINL peak, the discrepancy depending on the column efficiency.

To measure distribution isotherms by chromatography, the so-called *Elution by Characteristic Point (ECP)* method has been suggested. Retention volumes to several points on the curved flank of an experimental peak are measured and related to the solute concentration at those points. The distribution isotherm can then be calculated using Equation (1). The validity of the method depends on the efficiency of the column used for these measurements.

There is no known general way of calculating meaningful peak broadening parameters, such as plate numbers from NINL peaks. As the NINL case in practice is common, this observation is important: The usual equations for the calculation of plate numbers (such as those described in CN 3.10.03) should only be applied to effectively symmetrical peaks.

12D. Supercritical Fluid Chromatography and Extraction (IUPAC Recommendations 1993)

Prepared for publication by

R. M. Smith, Loughborough University of Technology, Loughborough, Leicestershire, UK

© 1993 IUPAC

Abstract

The report present definitions for the terms and symbols used when supercritical fluids are employed as the liquid phase in chromatography and allied areas including sample extraction. The terms supplement those in the general Nomenclature for Chromatography and includes additional more specific terms.

Introduction

Following the General Assembly Meeting in 1989 the Limited Life Time Commission for Chromatography and Other Analytical Separations took over the work on the nomenclature for chromatography that had previously been undertaken by the Commission for Analytical Nomenclature. A major part of the work was the Nomenclature for Chromatography which had been developed over a number of years by L. S. Ettre and has recently been published [1]. This work was comprehensive and included all the major areas of chromatography. Specialist chapters covered the specific areas of size exclusion chromatography and ion-exchange

chromatography. However, it was clear that as further new areas of separation science were developed specific terminologies of further additional terms and definitions would be needed.

Over the last few years the use of a supercritical fluid as the mobile phase in chromatography has become an accepted routine method. In the Nomenclature for Chromatography Ettre noted (1.4.04) "In general, the terms and definitions used for gas or liquid chromatography are equally applicable to supercritical-fluid chromatography". However, supercritical fluid chromatography has also lead to the use in the literature of a number of new terms whose meanings have been generally adopted by workers in the field. These new terms are formalized in the present Supplement to the general nomenclature of chromatography. Supercritical fluids have also been used for the extraction of samples and frequently similar equipment and operating conditions have been employed and many of the terms are also applicable in this field.

This nomenclature is designed to be used as a supplement to the principal nomenclature paper and is written as Section 7 of that paper [1]. It therefore omits any terms which have already been defined unless a new or additional definition has been necessary. The paper is also complementary to the definitions and terms for supercritical fluid chromatography recently published by ASTM [2].

*7. Special Terminology Used in Supercritical-Fluid Chromatography and Extraction

7.1 Basic Definitions

7.1.1 Critical temperature (T_c) The maximum temperature at which a gas can be converted into a liquid by an increase in pressure.

7.1.2 Critical pressure (p_c) The minimum pressure which would suffice to liquefy a substance at its critical temperature. Above the critical pressure, increasing the temperature will not cause a fluid to vaporize to give a two-phase system.

7.1.3 Critical point The characteristic temperature (T_c) and pressure (p_c) above which a gas cannot be liquefied.

7.1.4 Supercritical fluid The defined state of a compound, mixture or element above its critical pressure (p_c) and critical temperature (T_c).

7.1.5 Reduced temperature (T_r) The ratio of the temperature (T) in the system to the critical temperature (T_c)

$$T_r = T/T_c$$

7.1.6 Reduced pressure (p_r) The ratio of the pressure in the system (p) to the critical pressure (p_c).

$$p_r = p/p_c$$

7.2 The Mobile Phase

7.2.1 The *mobile phase* was defined previously in 1.1.06

7.2.2 Mobile-phase pressure

7.2.2.1 Outlet pressure (p_o) Defined as in 3.6.02.2. However, unlike gas and liquid chromatography the outlet pressure in supercritical-fluid chromatography has to be maintained above ambient pressure by a flow restrictor (7.3.1) or back-pressure regulator (7.3.2).

7.2.2.2 Pressure drop across the column (Δp) Defined as 3.6.02.3.

*For Sections 1–6 see *Pure & Appl. Chem.*, Vol. 65, No. 4, pp. 819–872, 1993.

7.2.3 Mobile-phase volume flow rate. Defined as 3.6.04. In supercritical-fluid chromatography this is usually quoted as the rate of delivery of the pumping system.

7.2.4 Mobile-phase mass flow rate The rate of mass flow through the column. It is usually determined by measuring the gas-flow rate (or liquid-flow rate) at ambient conditions after the mobile phase has been depressurized. If liquid modifiers are present in the mobile phase, corrections will be needed.

7.2.5 Mobile-phase composition The composition of the mobile-phase which is delivered to the column. This should be described in such a way that it can be reproduced in different laboratories. It can be expressed on a mass, volume, or mole fraction basis but in each case the temperature and pressure must also be defined.

If the individual components are pumped separately, the relative delivery flow rates should be defined.

Premixed eluents are often used and can be defined by their mass composition as recorded by the manufacturer. However, the delivered composition may depend on the relative volatility of the components and can change as a function of syringe pump volume and time.

7.2.5.1 Mobile-phase modifier Modifiers are materials (usually organic compounds such as methanol or acetonitrile) added to the supercritical fluid being used as the mobile phase to alter the elution properties.

7.3 Instrumentation

Most of the components of the instrumentation for supercritical-fluid chromatography are in common with liquid and gas chromatography and are defined in **Section 2.1 Apparatus for Column Chromatography**.

7.3.1 Flow restrictor This is a device which restricts the flow of the mobile phase leaving the column and is used to maintain the pressure in the chromatographic column.

7.3.1.1 Capillary restrictor This is a capillary tube which may be tapered or constricted and acts as a mass-flow controller. The column pressure is controlled by adjusting the pump flow rate.

7.3.1.2 Frit restrictor A frit placed at the end of an open-tubular column to act as a flow restrictor. Sometimes referred to as an *integral frit restrictor*.

7.3.2 Back-pressure regulator This is a device which is placed after the column and is used to regulate the pressure in the column by a pressure-adjustable diaphragm or controlled nozzle so that the same column-outlet pressure is maintained irrespective of the mobile-phase pump flow rate.

7.3.3 Sample injector as defined in 2.1.02. The most common form in supercritical-fluid chromatography is the *bypass injector* (see 2.1.02.2). In capillary supercritical-fluid chromatography a *timed injector* is often used.

7.3.3.1 Timed injector This is a form of *bypass injector* in which the rotation of the valve is timed so that only a portion of the contents of the sample loop can pass to the column.

7.3.4 High-pressure flow cell A flow-through cell (usually spectroscopic) designed for use at high pressures so that the sample remains dissolved in the mobile phase during detection.

7.4 The Chromatographic Medium

Supercritical-fluid chromatographic separations are carried out using capillary columns or packed columns similar to those used in gas or liquid chromatography (see **Section 3.1**). Stationary phases are usually chemically bonded to the support. Non-chemically bonded phases are often unsuitable as the stationary phase may be soluble in the mobile phase.

7.5 Terms Related to the Chromatographic Process

7.5.1 Isobaric separation Chromatographic separation carried out using constant inlet and outlet pressure conditions.

7.5.2 Isopycnic separation Chromatographic separations carried out using constant density conditions. The temperature and pressure may be altered during the run (originally the term *isoconfertic separation* was used but this term is not recommended).

7.5.3 Programmed elution A procedure in which the conditions of the separation are changed in a programmed manner. Unlike gas or liquid chromatography both the pressure and temperature can be programmed.

The term “*gradient elution*” should be restricted to changes in composition of the mobile phase with time (see 1.6.04).

7.5.3.1 Density-programmed elution A separation carried out using a pressure and/or temperature programme so that the density of the mobile phase changes with time in a pre-determined manner during the separation.

7.5.3.2 Pressure-programmed elution A separation carried out using a programmed increasing pressure with time.

7.5.3.3 Pressure/temperature-programmed elution A separation carried out using conditions where the pressure and temperature are programmed simultaneously. The temperature may be programmed to increase or decrease.

7.6 Coupled-systems

As well as discrete chromatographic detectors, supercritical-fluid chromatography has been coupled to more complex detectors and to other separation techniques and the most widely used are listed here.

7.6.1 Coupled supercritical-fluid chromatography-mass spectrometry (SFC-MS) Separation system in which the column effluent from a supercritical-fluid chromatograph is passed directly to the inlet chamber of a mass spectrometer.

7.6.2 Coupled supercritical-fluid chromatography-Fourier-transform infrared spectrometry (SFC-FTIR) Separation system in which the column effluent from a supercritical-fluid chromatograph is passed directly through a Fourier-transform infrared spectrometer.

7.6.3 Coupled supercritical-fluid chromatography-gas chromatography (SFC-GC) Separation system in which a fraction from the supercritical-fluid chromatograph effluent is transferred directly to the inlet port or column of a gas chromatograph system.

7.7 Supercritical-fluid Extraction

7.7.1 Supercritical-fluid extraction (SFE) Extraction of a material using a supercritical fluid. The extracted material is usually recovered by reducing the temperature or pressure of the extraction fluid and allowing the volatile components of the mobile phase to evaporate. Instrumentally supercritical-fluid extraction can use many of the components of a supercritical-fluid chromatographic system. It can be used either as an on-line sample introduction method for a chromatographic separation or as an off-line sample preparation method.

7.7.2 Coupled supercritical-fluid extraction-supercritical-fluid chromatography (SFE-SFC) System in which a sample is extracted with a supercritical-fluid which then places the extracted material in the inlet port of a supercritical-fluid-chromatographic system. The extract is then chromatographed directly using a supercritical fluid.

7.7.3 Coupled supercritical-fluid extraction-gas chromatography (SFE-GC) and Coupled supercritical-fluid chromatography-liquid chromatography (SFE-LC) System in which a sample is extracted using a supercritical fluid which is then depressurized to deposit the extracted material in the inlet port or column of a gas or liquid chromatographic system, respectively. The extract is then chromatographed directly.

Table 1 Index of additional terms

Back-pressure regulators	7.3.2
Capillary restrictors	7.3.1.1
Coupled supercritical-fluid chromatography-mass spectrometry	7.6.1
Coupled supercritical-fluid extraction-Fourier-transform infrared spectroscopy	7.6.2
Coupled supercritical-fluid chromatography-gas chromatography	7.6.3
Coupled supercritical-fluid extraction-gas chromatography	7.7.3
Coupled supercritical-fluid extraction-liquid chromatography	7.7.3
Coupled supercritical-fluid extraction-supercritical-fluid chromatography	7.7.2
Critical point	7.1.3
Critical pressure	7.1.2
Critical temperature	7.1.1
Density-programmed elution	7.5.3.1
Flow restrictors	7.3.1
Frit restrictor	7.3.1.2
High-pressure flow cell	7.3.4
Integral frit restrictor	7.3.1.2
Isobaric separation	7.5.1
Isopycnic separation	7.5.2
Mobile-phase composition	7.2.5
Mobile-phase modifiers	7.2.5.1

^aThe Particle Data Group recommends the use of italic symbols for particles and this has been adopted by many physicists.

^bThe electron as β -particle is sometimes denoted by β .

^cThe value is given in Bohr magnetons μ/μ_B , $\mu_B = eh/2m_e$.

^dThe value is given as μ/μ_μ , where $\mu_\mu = eh/2m_\mu$.

(Reprinted with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford: Blackwell Scientific Publications.)

In nuclear physics and chemistry the masses of particles are often quoted as their energy equivalents (usually in mega electronvolts). The unified atomic mass unit corresponds to 931.494 32 (28) MeV.

Atom-like pairs of a positive particle and an electron are sometimes sufficiently stable to be treated as individual entities with special names.

*Examples*positronium (e^+e^-) $m(e^+e^-) = 1.097\,152\,503(26) \times 10^{-3}u$ muonium (μ^+e^- ; Mu) $m(\text{Mu}) = 0.113\,977\,478(17)u$

The positive or negative sign for the magnetic moment of a particle implies that the orientation of the magnetic dipole with respect to the angular momentum corresponds to the rotation of a positive or negative charge respectively.

Standard Atomic Weights of the Elements 1991

As agreed by the IUPAC Commission on Atomic Weights and Isotopic Abundances in 1979 the relative atomic mass (atomic weight) of an element, E , can be defined for any specified sample. It is the average mass of its atoms in the sample divided by the unified atomic mass unit* or alternatively the molar mass of its atoms divided by the standard molar mass $M^\theta = Lm_u = 1\text{ g mol}^{-1}$:

$$A_r(E) = \bar{m}_a(E)/u = M(E)M^\theta$$

The variations in isotopic composition of many elements in samples of different origin limit the precision to which a relative atomic mass can be given. The standard atomic weights revised biennially by the IUPAC Commission on Atomic Weights and Isotopic Abundances are meant to be applicable for normal materials. This means that to a high level of confidence the relative atomic mass of an element in any normal sample will be within the uncertainty limits of the tabulated value. By 'normal' it is meant here that the material is a reasonably possible source of the element or its compounds in commerce for industry and science and that it has not been subject to significant modification of isotopic composition within a geologically brief period. This, of course, excludes materials studied themselves for very anomalous isotopic composition.

The relative atomic masses of many elements depend on the origin and treatment of the materials. The notes to this table explain the types of variation to be expected for individual elements.

A value in brackets denotes the mass number of the most stable isotope. ρ denotes density, $\theta_{c,m}$ denotes melting temperature, $\theta_{c,b}$ denotes boiling temperature and c_p denotes specific heat capacity. subl. denotes sublimes.

Element	Symbol	Atomic number	Relative atomic mass	ρ (g cm ⁻³)	$\theta_{c,m}$ (°C)	$\theta_{c,b}$ (°C)	c_p (J kg ⁻¹ K ⁻¹)	Oxidation states	Note

(g) geologically exceptional specimens are known in which the element has an isotopic composition outside the limits for normal material. The difference between the average relative atomic mass of the element in such specimens and that given in the table may exceed considerably the implied uncertainty.

(m) modified isotopic compositions may be found in commercially available material because it has been subjected to an undisclosed or inadvertent isotopic separation. Substantial deviations in relative atomic mass of the element from that given in the table can occur.

(r) range in isotopic composition of normal terrestrial material prevents a more precise relative atomic mass being given; the tabulated $A_r(E)$ value should be applicable to any normal material.

(A) Radioactive element that lacks a characteristic terrestrial isotopic composition.

(Z) An element without stable nuclide(s), exhibiting a range of characteristic terrestrial compositions of long-lived radionuclide(s) such that a meaningful relative atomic mass can be given.

(U) The names and symbols given here are systematic and based on the atomic numbers of the elements as recommended by the IUPAC Commission on the Nomenclature of Inorganic Chemistry. The names are composed of the following roots representing digits of the atomic number:

1 un,	2 bi,	3 tri,	4 quad,	5 pent,
6 hex,	7 sept,	8 oct,	9 enn,	0 nil

The ending -ium is then added to the three roots. The three-letter symbols are derived from the first letters of the corresponding roots. (Reprinted with permission from Mills *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn. Oxford Scientific Publications.)

Properties of Nuclides

The table contains the following properties of naturally occurring and some unstable nuclides:

Column

1. Z is the atomic number (number of protons) of the nuclide.
2. Symbol of the element.
3. A is the mass number of the nuclide. The * sign denotes an unstable nuclide (for elements without naturally occurring isotopes it is the most stable nuclide) and the # sign a nuclide of sufficiently long lifetime to enable the determination of its isotopic abundance.
4. The atomic mass is given in unified atomic mass units, $u = m_a(^{12}\text{C})/12$, together with the standard errors in parentheses and applicable to the last digit quoted.
5. Isotopic abundances are given as mole fractions, x , of the corresponding atoms in percents. They were recommended in 1989 by the IUPAC Commission on Atomic Weights and Isotopic Abundances. The uncertainties given in parentheses are applicable to the last digits quoted and cover the range of probable variations in the materials as well as experimental errors.
6. I is the nuclear spin quantum number.
7. Under magnetic moment the maximum z -component expectation value of the magnetic dipole moment, m , in nuclear magnetons is given. The positive or negative sign implies that the orientation of the magnetic dipole with respect to the angular momentum corresponds to the rotation of a positive or negative charge, respectively. An asterisk * indicates that more than one value is given in the original compilation. The value of highest precision or most recent data is given here.
8. Under quadrupole moment, the electric quadrupole moment area is given in units of square femtometres, $\text{fm}^2 = 10^{-30} \text{ m}^2$, although most of the tables quote them in barns ($1 \text{ barn} = 10^{-28} \text{ m}^2 = 100 \text{ fm}^2$). The positive sign implies a prolate nucleus, the negative sign an oblate nucleus. The data for $Z \leq 20$ were taken from the compilation by P. Pykkö with values for Cl and Ca corrected by D. Sundholm (private communication), and the others from P. Raghavan. An asterisk* indicates that more than one value is given in the original compilation.

1,2-Dimethoxyethane	240		
<i>N,N</i> -Dimethylacetamide	268	59	(83°C)
<i>N,N</i> -Dimethylformamide	270	36.7	
Dimethyl sulphoxide	265	4.7	
1,4-Dioxane	215	2.209	(25°C)
Diethyl ether	218	4.335	
Ethanol	210	24.30	(25°C)
2-Ethoxyethanol	210		
Ethyl acetate	255	6.02	(25°C)
Glycerol	207	42.5	(25°C)
<i>n</i> -Hexadecane	200	2.06	(25°C)
<i>n</i> -Hexane	210	1.890	
Methanol	210	32.63	(25°C)
2-Methoxyethanol	210	16.9	
Methyl cyclohexane	210	2.02	(25°C)
Methyl ethyl ketone	330	18.5	
Methyl isobutyl ketone	335		
2-Methyl-1-propanol	230	1	
<i>N</i> -Methyl-2-pyrrolidone	285	32.0	
Pentane	210	1.844	
<i>n</i> -Pentyl acetate	212		
1-Propanol	210	20.1	(25°C)
2-Propanol	210	18.3	(25°C)
Pyridine	330	12.3	(25°C)
Tetrachloroethylene ^b	290		
Tetrahydrofuran	220	7.6	
Toluene	286	2.379	(25°C)
1,1,2-Trichloro-1,2,2-trifluoroethane	231		
2,2,4-Trimethylpentane	215	1.936	(25°C)
<i>o</i> -Xylene	290	2.568	
<i>m</i> -Xylene	290	2.374	
<i>p</i> -Xylene	290	2.270	
Water		78.54	(25°C)

^a Stabilized with ethanol to avoid phosgene formation.

^b Stabilized with thymol (isopropyl meta-cresol).

16. STATISTICAL TABLES

The following tables are presented in a format that is compatible with the needs of analytical chemists: the significance level $P = 0.05$ has been used in most cases, and it has been assumed that the number of measurements available is fairly small. Except where stated otherwise, these abbreviated tables have been taken, with permission, from *Elementary Statistics Tables* by Henry R. Neave, published by George Allen & Unwin Ltd. (Tables 1–3, 5–6, and 7–11). The reader requiring statistical data corresponding to significance levels and/or numbers of measurements not covered in the tables is referred to these sources.

Table 1 The t -distribution

Value of $ t $ for a confidence interval of: Critical value of t for P values of: Number of degrees of freedom	90% 0.10	95% 0.05	98% 0.02	99% 0.01
1	6.31	12.71	31.82	63.66
2	2.92	4.30	6.96	9.92
3	2.35	3.18	4.54	5.84
4	2.13	2.78	3.75	4.60
5	2.02	2.57	3.36	4.03
6	1.94	2.45	3.14	3.71
7	1.89	2.36	3.00	3.50
8	1.86	2.31	2.90	3.36
9	1.83	2.26	2.82	3.25
10	1.81	2.23	2.76	3.17
12	1.78	2.18	2.68	3.05
14	1.76	2.14	2.62	2.98
16	1.75	2.12	2.58	2.92
18	1.73	2.10	2.55	2.88
20	1.72	2.09	2.53	2.85
30	1.70	2.04	2.46	2.75
50	1.68	2.01	2.40	2.68
∞	1.64	1.96	2.33	2.58

The critical values of $|t|$ are appropriate for a *two*-tailed test. For a *one*-tailed test the value is taken from the column for *twice* the desired P -value, e.g. for a one-tailed test, $P = 0.05$, 5 degrees of freedom, the critical value is read from the $P = 0.10$ column and is equal to 2.02.

Table 2 Critical values of F for a one-tailed test ($P = 0.05$)

v_1 : v_2	1	2	3	4	5	6	7	8	9	10	12	15	20

15	0.000	0.000	0.004	0.018	0.059	0.151	0.304	0.500

The table uses the binomial distribution with $P = 0.5$ to give the probabilities of r or less successes for $n = 4$ –15. These values correspond to a one-tailed sign test and should be doubled for a two-tailed test.

Table 7 Wilcoxon signed rank test. Critical values for the test statistic at $P = 0.05$

n	One-tailed test	Two-tailed test
5	0	NA
6	2	0
7	3	2
8	5	3
9	8	5
10	10	8
11	13	10
12	17	13
13	21	17
14	25	21
15	30	25

The null hypothesis can be rejected when the test statistic is \leq the tabulated value. NA indicates that the test cannot be applied.

Table 8 Wilcoxon rank sum test; Mann-Whitney U -test. Critical values for U or the lower of T_1 and T_2 at $P = 0.05$

n_1	n_2	One-tailed test	Two-tailed test
3	3	0	NA
3	4	0	NA
3	5	1	0
3	6	2	1

Critical values for one-tailed and two-tailed tests at $P = 0.05$. The appropriate value is compared with the maximum difference between the experimental and theoretical cumulative frequency curves.

17. THIN LAYER (PLANAR) CHROMATOGRAPHY: DETECTION

A. Misra, Bareilly, India

Copyright © 2000 Academic Press

The following tables list detection methods and reagents suitable for detecting and identifying substances separated by thin-layer (planar) chromatography.

Table 1.1 Methods of detection on TLC plates (aluminium oxide) by heating (Types 150/T or 60/E)

<i>Substances</i>	<i>Temperature/time</i>	<i>Remarks</i>
Pesticides, e.g. aminocarb, captan, difolatan, landrin, rotenone	200°C, 45 min	Induction of fluorescence in weakly fluorescent or nonfluorescent pesticides and amplification of natural fluorescence. There are some differences between basic and acidic aluminium oxide layers
Δ^4 -3-Ketosteroids, e.g. testosterone and <i>epi</i> -testosterone in urine	180°C, 20 min	Pale blue induced fluorescence ($\lambda_{fl} = 440$ nm) for Δ^4 -3-ketosteroids, detection limit: 5 ng
Δ^4 -3-Ketosteroids, e.g. trimethylsilyl-testosterone	180°C, 20 min or 150°C, 20 min	Conversion of Δ^4 -3-ketosteroids or their trimethylsilyl or acetyl derivatives in fluorescent components, whereby the detection limits were improved by 65% for the acetates. Δ^5 -3-keto- and Δ^5 -3-OH-steroids also react with the same sensitivity
Testosterone	180°C, 20 min	Induced fluorescence ($\lambda_{fl} > 430$ nm, cut off filter) by thermal treatment of the chromatogram, the fluorescence increased by a factor of 2.5 by dipping in a solution of Triton X-100 – chloroform (1 + 4). Working range: 2–50 ng substance per chromatogram zone. Prewashing the layers with methanol-ammonia solution (25%) (50 + 50) increased the precision
Testosterone	180°C, 20 min	Induced fluorescence and fluorescence amplification by a factor of 25 by dipping the chromatogram in a solution of Triton X-100 – chloroform (1 + 4)
Δ^4 -3-Ketosteroids, e.g. progesterone in plasma	150°C, 20 min	Conversion of Δ^4 -3-ketosteroids into fluorescent derivatives ($\lambda_{fl} = 440$ nm). Relatively selective for progesterone at 150°C detection limit: 2–5 ng

Table 1.2 Methods of fluorimetric detection on TLC plates (silica gel) by heating

<i>Substances</i>	<i>Temperature/time</i>	<i>Remarks</i>
Essential oil components	800–900°C	Induction of fluorescence in a special apparatus
Steroids, e.g. cholesterol, triolein, androsterone; sugars, e.g. fructose, glucose, ribose; amino acids, pyrimidines, purines, alkaloids	110–150°C, 2–12 h	Conversion to fluorescent derivatives by heating
Alkaloids, e.g. raubasine and its metabolites in plasma, urine and bile	120°C, 1 h	Amplification of the natural fluorescence of raubasine ($\lambda_{fl} = 482$ nm), detection limit 20 ng
Alkaloids, e.g. reserpine, rescinnamine	105°C, 2 h	Induced fluorescence ($\lambda_{fl} > 500$ nm, cut off filter). Possibly formation of 3-dehydro derivatives
Alkaloids, e.g. reserpine, ajmaline, rescinnamine	105°C, 2 h or 105°C, 15 h	Induction of stable fluorescence ($\lambda_{fl} > 480$ nm, cut off filter), detection limits 5–20 ng
Alkaloids, e.g. cocaine, ecgonine, benzoylecgonine, ecgonine methyl ester	280°C, 8 min or 260°C, 10–30 min	Pale blue induced fluorescence ($\lambda_{fl} > 390$ nm, cut off filter), fluorescence amplification by a factor of 2 on dipping in liquid paraffin solution; detection limits: < 10 ng
Alkaloids, e.g. lupanine, angustifoline, sparteine, lupinine, hydroxylupanine	130°C, 17–35 h	Induced blue fluorescence ($\lambda_{fl} = 400$ nm), detection limits: 10 ng
Pesticides, e.g. dursban, azinphos-methyl, menazon, imidan, phosalone, zinophos	200–225°C, 20–120 min	Induced fluorescence or amplification of natural fluorescence; detection limits: 10–300 ng
Organophosphorus pesticides, e.g. coumaphos, menazon, maretin, dursban	200°C, 45 min	Induced fluorescence or amplification of natural fluorescence, detection limits: 1–80 ng
Pesticides, e.g. fuberidazol	200°C, 45 min	Amplification of the natural fluorescence of some pesticides and bathochromic shift of the excitation and emission maxima; detection limits: 5–100 ng
Pesticides, e.g. coumatetralyl, methabenzthiazuron, propylisom, naptalam, thioquinox, warfarin etc.	200°C, 45 min	Induced fluorescence ($\lambda_{fl} > 430$ nm, cut off filter); detection limits: 6–600 ng
Coumaphos	200°C, 20 min	Residue analysis; induced fluorescence on heating ($\lambda_{fl} > 400$ nm); detection limit: 1 ng
Potasan, coumaphos, coroxon	200°C, 20 min	Induced blue fluorescence ($\lambda_{fl} = 430$ nm or 450 nm), identification of the fluorescent derivatives as chlorferon or 4-methylumbelliferone
Coumaphos	200°C, 20 min	Residue determination in honey, induced fluorescence ($\lambda_{fl} > 400$ nm, cut off filter); detection limit: 0.5 ng
Rubratoxin B	200°C, 10 min	Induced fluorescence that can be intensified by gassing the previously heated chromatogram plates with ammonia vapours (10 min). This also alters the colour of the emitted light to pale blue
Glucose or methylglucosides	135°C, 3 min or 140°C, 10 min	Induced yellow fluorescence
Sugar derivatives	'Mild heating over a Bunsen burner'	No details of whether fluorescence was produced or if a carbonization reaction occurred
Sugars, e.g. glucose, fructose, galactose, mannose etc.	160°C, 10 min	Production of fluorescence by heating the chromatogram after covering it with a glass plate. Sugar alcohols and C ₁ –C ₁ bonded oligosaccharides do not react; detection limit: 10 ng

Table 1.2 *Continued*

<i>Substances</i>	<i>Temperature/time</i>	<i>Remarks</i>
Sugars, e.g. glucose, glucosamine, fucose, raffinose, cellobiose, methylated sugars	80 → 260°C, gradient or 200°C, 5 min	Production of fluorescence by temperature gradients (10°C/30 s) to determine the optimum heating temperature for the individual substances. Oligosaccharides require higher temperatures than monosaccharides. Detection limit: 1 nMol. The fluorescence colours are characteristic particularly for the methylated sugars
Lipids, e.g. β -sitosterol, geraniol, dolichol, squalene, cholesterol	200°C, 15 min	Induced fluorescence; detection limits: < 1 μ g cholesterol
C-Nucleosides	Moderate heating on a hot plate	No details of whether fluorescence or carbonization was produced
Nomifensine and metabolites	70°C, 2 h + UV ₂₅₄	Heating and simultaneous UV irradiation produced intense yellow fluorescence ($\lambda_{fl} > 460$ nm, cut off filter)

Reproduced with permission from, Jork H, Funk W, Fisher W and Wimmer H (1994). *Thin Layer Chromatography: Regents and Detection Methods*, volume 1B. Weinheim: Wiley VCH.

Table 1.3 Examples of fluorimetric detection after thermal treatment of layer after chromatography

<i>Substances</i>	<i>Temperature/time</i>	<i>Remarks</i>
Sugars, e.g. lactose, glucose, fructose	120°C, 15 min	Violet fluorescence on a dark blue background
Sugars, e.g. lactose, glucose, fructose	120°C, 15 min	Induced fluorescence; detection limits in nanogram range
Glucose, fructose	Infrared lamp or 170°C each for 3 min	Heating produced stable bluish-white fluorescence ($\lambda_{exe} = 365$ nm and $\lambda_{fl} > 400$ nm, cut off filter K 400), detection limits; 5–10 ng
Sugars, e.g. glucose, rhamnose, xylose etc.	160°C, 3–4 min or infrared lamp	Induction of brilliant stable fluorescence $\lambda_{exe} = 365$ nm and $\lambda_{fl} > 400$ nm (cut off filter K 400), sugar alcohols do not fluoresce; detection limits; 5–10 ng
Creatine, creatinine, uric acid in urine and serum	150°C, 3–4 min	Stable fluorescence $\lambda_{exe} = 365$ nm and $\lambda_{fl} > 400$ nm (cut off filter K 400)
Sugars, e.g. sucrose, ribose, xylose	150°C, 3–4 min	Induced fluorescence $\lambda_{exe} = 365$ nm and $\lambda_{fl} > 400$ nm (cut off filter K 400)

Reproduced with permission from, Jork H, Funk W, Fisher W and Wimmer H (1994). *Thin Layer Chromatography: Regents and Detection Methods*, volume 1B. Weinheim: Wiley VCH.

Table 2 Some substances that produce intense fluorescence when treated with ionized nitrogen after they have been chromatographed

<i>Substance</i>	<i>Exposure time [s]</i>	<i>Substance</i>	<i>Exposure time [s]</i>
Cholesterol	60	Oleic acid	180
Cholesteryl pelargonate	60	Morphine	180
Progesterone	60	Codeine	180
Testosterone	60	Cocaine	180
Dieldrin	60	Dimerol	180
Tetrahydrocannabinol	60	Phenobarbital	180
Inositol	60	Chlorpromazine	180
Lauryl alcohol	180	d-Amphetamine sulfate	180
<i>n</i> -C ₂₂ H ₄₆	180	Methadone	180
Phenol	180

Table 3 Reagents suitable for the recognition of functional groups

<i>Functional group</i>	<i>Reagent</i>	<i>Remarks</i>
Acetylene compounds	Dicobaltoctacarbonyl	Formation of coloured complexes. After the reagent excess has been washed out, reaction with bromine vapour yields cobalt bromide, which reacts with α -nitroso- β -naphthol to yield red chromatogram zones on an almost colourless background
Aldehydes	4-Amino-3-hydrazino-5-mercapto-1,2,4-triazole (Purpald reagent)	Aldehydes yield violet chromatogram zones on a whitish-yellow background. Some alcohols form yellow to orange-coloured chromatogram zones
Aldehydes	2,4-Dinitrophenylhydrazine	Formation of coloured hydrazones or osazones. It is possible to distinguish between saturated and unsaturated hydrazones using potassium hexacyanoferrate (III)
Aldehydes	Hydrazine sulfate + hydrochloric acid	Aromatic aldehydes yield coloured hydrazones
Alcohols	4-(4-Nitrobenzyl)pyridine	Amino compounds, esters and ethers do not interfere, but phenols and acids as well as epoxides, olefins and substances containing labile halogen probably do
Alcohols (diols, polyols, sugars)	Lead(IV) acetate – dichlorofluorescein	Diol cleavage of vicinal diols, e.g. sugars, sugar alcohols. The lead tetraacetate consumed is no longer available to decompose the fluorescent dichlorofluorescein
Amines (primary)	Ninhydrin	Reddish or bluish chromatogram zones are produced, amino sugars and amino acids also react. Unexpectedly ascorbic acid also reacts
Amines (primary aliphatic and aromatic)	Diphenylboric anhydride + salicylaldehyde (DOOB)	Fluorescent reaction products are produced
Amines (primary)	α -Phthalaldehyde (OPA)	In the presence of mercaptoethanol α -phthalaldehyde reacts with primary amines and amino acids to yield fluorescent isoindole derivatives

Table 3 *Continued*

<i>Functional group</i>	<i>Reagent</i>	<i>Remarks</i>
Amines (primary)	Trinitrobenzenesulfonic acid (TNBS)	On heating primary amines react with TNBS to yield intensely coloured Meisenheimer complexes. Amino acids also react
Amines (primary)	Fluorescamine	Primary aliphatic and aromatic amines yield fluorescent derivatives. Primary aromatic amines yield stable yellow-coloured derivatives that can be eluted from the TLC layer
Amines (primary aromatic)	Sodium nitrite + α -naphthol or Bratton-Marshall reagent	Diazotization of the primary amine followed by coupling with α -naphthol or N-(L-naphthyl)ethylenediamine. Sulfonamides also react
Amines (primary aromatic)	4-(Dimethylamino)benzaldehyde + acid	Alkaloids and indole derivatives also react
Amines (capable of coupling)	Fast blue salt B, fast blue salt BB, fast black salt K, diazotized sulfanilic acid (Pauly's reagent), diazotized sulfanilamide or 4-nitroaniline	Intensely coloured azo dyes are produced. Catecholamines, imidazoles and phenols also react
Amines (primary and secondary)	7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride)	Fluorescent 4-nitrobenzofurazan derivatives are produced. Phenols and thiols also react
Amines (primary and secondary aromatic)	<i>p</i> -Chloranil	The reaction depends on the catalytic effect of silica gel. Monochlorobenzene as solvent for the reagent, also contributes. There is no reaction on cellulose layers
Amines (secondary aliphatic and alicyclic)	Sodium nitroprusside + acetaldehyde	Secondary aliphatic and alicyclic amines yield blue-coloured chromatogram zones (e.g. morpholine, diethanol amine)
Amines (long-chain primary, secondary and tertiary plus quaternary ammonium salts)	Cobalt(II) thiocyanate	Long-chain primary, secondary and tertiary amines and long-chain quaternary ammonium salts yield blue chromatogram zones on a pink background
Carboxyl groups (carboxylic acids)	Indicators, e.g. bromocresol green, bromocresol green + bromophenol blue + potassium permanganate, bromocresol purple, methyl red + bromothymol blue	Detection depends on the colour change of the indicator in acid medium. Quaternary ammonium salts give a colour change in some cases
Carboxyl groups (carboxylic acids)	2,6-Dichlorophenol-indophenol (Tillmann's reagent)	Organic acids release the red undissociated acid from the blue mesomerically stabilized phenolate anion. Reductones reduce the reagent to a colourless compound
Carboxyl groups (carboxylic acids)	Aniline + aldose (e.g. glucose)	The action of acid causes glucose to be converted to furfural which reacts with aniline to yield a coloured product
Halogen derivatives	Silver nitrate, ammoniacal (Dedonder's, Tollens' or Zaffaroni's reagent)	Halogen compounds yield black chromatogram zones on a pale grey background
Ketones	2,4-Dinitrophenylhydrazine	Formation of coloured hydrazones or osazones. It is possible to distinguish between saturated and unsaturated hydrazones using potassium hexacyanoferrate (III)

Table 3 *Continued*

<i>Functional group</i>	<i>Reagent</i>	<i>Remarks</i>
Nitro derivatives	Benzylcyanide + benzyl-trimethylammonium hydroxide	Nitro compounds, e.g. explosives, or pesticides containing nitro groups yield gray to bluish-green chromatogram zones on a brownish background
Peroxides	1-Naphthol + N ⁴ -ethyl-N ⁴ - (2-methanesulfonamidoethyl)-2-methyl-1,4-phenylenediamine (peroxide reagent)	A quinonimine dyestuff is produced on reaction with peroxides
Peroxides	Iron(II) sulfate + ammonium thiocyanate	Peroxides rapidly oxidize iron(II) to iron(III) ions which react to yield brown-red iron(III) thiocyanate complexes
Peroxides	Potassium iodide + starch	Peroxides release free iodine which forms a blue complex with the starch
Peroxides	N,N-Dimethyl-1,4-phenylenediamine (N,N-DPDD), N,N,N',N'-tetra-methyl-1,4-phenylene-diamine (TPDD)	Peroxides, e.g. alkyl hydroperoxides, oxidize N,N-DPDD to Wurster's red and TPDD to Wurster's blue
Phenols	7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride)	Fluorescent 4-nitrobenzofuran derivatives are produced. Primary and secondary aromatic amines and thiols also react
Phenols (capable of coupling)	Fast blue salt B, fast blue salt BB, fast black salt K, diazotized sulfanilic acid (Pauly's reagent) diazotized sulfanilamide or 4-nitroaniline	Intensely coloured azo dyes are formed. Catecholamines, imidazoles and amines capable of coupling also react
Thiols, thioethers, disulfides	Sodium metaperiodate + benzidine	Substances with divalent sulfur yield white chromatogram zones on a blue background
Thiols	7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride)	Fluorescent 4-nitrobenzofuran derivatives are formed. Primary and secondary aromatic amines and phenols also react

The range of electromagnetic radiation. The lower part is an enlargement of the UV-visible region

Colour Plate 1

Plate 1 Affinity Separation Computer-generated model of the molecular structure of Interleukin-2 (IL-2), created using data from crystallographic studies. IL-2 is used to artificially boost the immune response against certain human cancers. It is released by certain key cells of the immune system (T-lymphocytes) that have been activated by foreign antigens. IL-2 amplifies the proliferation of other types of T-cells - particularly the “killer” T-cells that attack cancer cells directly. In one immunotherapy technique, blood is removed from a cancer victim, doped with IL-2 and cultured *in vitro* to raise the population of T-cells. The product is then reinjected into the patient. (With permission from J. C. Revy / Science Photo Library.)

Colour Plate 2

Plate 2 Centrifugation The Swedish physical chemist, Theodor Svedberg, 1884-1971. Svedberg studied at Uppsala and stayed at this university for life. Chiefly interested in the chemistry of colloids (a suspension of large particles) and how best to separate out floating giant molecules, he developed the ultracentrifuge. Spinning at high speed a powerful enough centrifugal force will affect large molecules and purify out proteins. Svedberg, in this way, calculated the relative molecular mass of haemoglobin. For this technique and for his other work on colloids, Svedberg was awarded the Nobel Prize for chemistry in 1926. The unit of sedimentation velocity, the *svedberg* (S) is named after him. (With permission from Science Photo Library.)

Colour Plate 3

Plate 3 Chromatography Archer Martin (b.1910), British chemist and Nobel Laureate. Martin studied at Cambridge, gaining his doctorate in 1938 before performing research on vitamins. He later joined the staff of the Wool Industries Research Association where he met R.L.M Synge. Whilst looking into the problem of separating complex mixtures of amino acids, Martin and Synge developed partition Chromatography. By 1944, Martin had advanced the technique to combine both partition and absorption methods – and discovered paper Chromatography. This powerful analytical method won Martin and Synge the 1952 Nobel Prize for Chemistry. Photographed in 1993. (With permission from Nick Sinclair / Science Photo Library.)

Colour Plate 4

Plate 4 Crystallization Ice Crystals. Polarised light micrograph of a thin sheet of ice. The ice appears to have many colours within it. These are *birefringence* patterns due to different wavelengths of plane polarised light being rotated by different amounts. These colours indicate strong internal tensions in the ice, a result of the outer layers of ice freezing before the inner regions and therefore introducing stress into the crystal structure. Magnifications: unknown. (With permission from Adrienne Hart-Davis / Science Photo Library.)

Colour Plate 5

Plate 5 Distillation Illustration of a sixteenth century alcohol distillation set up showing two boiling vessels (bottom), the central column, or rectifying column, containing cold water & two receiving vessels (top). The illustration was produced by one Ulstadius in 1526. There is no further information on him or the publication. (With permission from Dr Jeremy Burgess / Science Photo Library.)

Colour Plate 11

Plate 11 Flotation A sample of native (naturally occurring) copper. Native copper usually occurs in compact, filiform or dendritic masses, although tetrahedral or octahedral crystals are occasionally found. (With permission from J. C. Revy / Science Photo Library.)

Colour Plate 12

Plate 12 Mass Spectrometry Time-of-flight secondary ion mass spectrometer. View of a sample tray of a time-of-flight secondary ion mass spectrometer (TOF SIMS). This mass spectrometer analyses the surface of a sample. A pulsed ion beam is used to remove molecules from the outermost surface of the sample and convert them to ions. This is done at low intensity so that large or “macro” molecules, such as polymers, stay intact. The ions are taken up into a flight tube and accelerated toward a detector. The time taken to reach the detector determines the mass of the ion. This mass spectrometer helps to accurately determine the chemical composition of a sample’s surface. (With permission from Tek Image / Science Photo Library.)

Colour Plate 13

Plate 13 Centrifugation View of a centrifuge in operation. Centrifuges separate samples into their components by spinning them in tubes at high speed. The force of spinning pushes the densest matter to the very bottom of the tube. (With permission from Tek Image / Science Photo Library.)

Colour Plate 14

Plate 14 Centrifugation A centrifuge used to separate the various components in the blood. The liquid is placed into a container that is spun at high speed around a central axis; the centrifugal force separates groups of particles with different densities. Blood is separated into red cells, white cells and plasma. (With permission from Chris Priest / Science Photo Library.)

Colour Plate 15

Plate 15 Affinity Separation: Rational Design, Synthesis and Evaluation Illustration of the molecular model of porcine pancreatic kallikrein with the dipeptidyl motif Arg-Phe occurring in the natural kallikrein substrate, kinioge complex using Quanta 97. The residues in the BPTI inhibitor not involved in the complex were deleted, leaving residues Lys-15 and Cys-14, which were substituted with arginine and phenylalanine respectively. The dipeptide was energy-minimized and its side chains were adjusted to interact with the primary and secondary binding sites, as the Lys-Cys dipeptide does in the BPTI-porcine pancreatic kallikrein complex.

Colour Plate 16

Plate 16 Affinity Separation: Rational Design, Synthesis and Evaluation Illustration of the synthetic ligand docked in the substrate-binding site of porcine pancreatic kallikrein. The ligand is an analogue of the Arg-Phe dipeptide that occurs in the natural substrate of kallikrein, kininogen, and is responsible for the enzyme-substrate complex. The benzamidine and phenethylamine moieties substituted on a triazine framework mimic the Arg-Phe dipeptide. The ligand was designed and energy-minimized in Quanta 97 and moved in the vicinity of the substrate-binding site, whence the side chains were adjusted to fit in the primary and secondary binding sites in porcine kallikrein. The aromatic ring of phenethylamine stacks in the primary binding site between Tyr-99 and Trp-215 and the benzamidine group forms several interactions with Asp-189, Ser-226, Gly-216, Pro-217 and Thr-218, forming the secondary binding site.

Colour Plate 17

Plate 17 Affinity Separation: Rational Design, Synthesis and Evaluation. The complex between the Fb fragment of SpA and Fc fragment of IgG. The residues in pink represent amino acids in SpA interacting with the residues inter- and intramolecular hydrogen bonding. The interaction involves a total of 32 amino acids spanning an intersurface area corresponding to 40nm^2 . The interaction is predominantly characterized by hydrophobic interactions as well as some hydrogen bonding and two salt bridges.

Colour Plate 18

Plate 18 Affinity Separation: Rational Design, Synthesis and Evaluation Molecular model between the Fc fragment of IgA and the synthetic ligand ApA. The ligand, in red, is a mimic of the key dipeptide Phe-Tyr, in green, in SpA and comprises anrfino and tyramino moieties substituted on a triazinyl framework. ApA is located at the putative binding site among the amino acid residues involved in the interaction between the Fc part of IgG and fragment of SpA.

Colour Plate 19

Plate 19 Chromatography: Gas Chromatography column. Technician examining a chromatography column leading into a mass spectrometer. The column is packed with small beads which separate the sample into different fractions. The fractions are then run into the mass spectrometer, which ionises and fragments the molecules. The amount the fragments deviate is indicative of their mass and charge. This can provide detailed information on the fractions' structures. This technique can be used to study many volatile molecules. (With permission from James King-Holmes / Science Photo Library).

Colour Plate 20

Colour Plate 21

Plate 21 Chromatography: Liquid Radial compression column cartridge. Radial compression is a technique used in high pressure liquid Chromatography whereby an external pressure is applied to the outside of the column. This ensures that the column walls remain in intimate contact with the particles of stationary phase contained within the column. This prevents the formation of voids that would reduce the chromatographic performance of the system.

Colour Plate 22

Plate 22 Chromatography: Liquid Light micrograph in interference contrast illumination of particles used in a high-pressure liquid Chromatography (HPLC) column. These tiny particles use strong anionic exchange (SAX) to cause the change in movement rates of the liquid's components through the HPLC column. SAX involves the exchange of a negative ion of a component in the liquid with a similarly charged ion in the column particles. Non-ionic components, or those with ionic charges different to that of the particles, are unaffected. Magnification x200 at 35mm size. (With permission from Andrew Syred / Science Photo Library).

Colour Plate 23

Plate 23 Chromatography: Liquid Large-Scale Liquid Chromatography. Scientist with column Chromatography equipment. Column Chromatography is used to separate the various components from a mixture of chemicals. During this process the mixture is put in the top of the column. The mixture passes through a porous substance, which selectively hinders the movement of each of the components. This means that some components will travel further in a given time than others, allowing each of them to be individually collected. Photograph of equipment used to isolate chemicals produced by microorganisms, including genetically engineered varieties. (With permission from Maximilian Stock Ltd / Science Photo Library).

Colour Plate 24

Plate 24 Chromatography: Liquid Chromatography is used to separate enantiomers. (R) – lactic acid. Computer illustration of a molecule of (R) – lactic acid (formula: $C_3H_6O_3$). Atoms are represented as cylinders and are colour-coded: carbon (yellow), hydrogen (white) and oxygen (red). Four different groups are joined to the central carbon atom here, a property known as chirality. The groups are given priorities based on their atomic number, and the molecule is viewed along the line of the bond to the lowest priority group. The order of the other groups decreasing priorities determines whether the isomer is classified as R (clockwise as here) or S (anti-clockwise). (With permission from Prof. K. Seddon / Science Photo Library).

Colour Plate 25

Plate 25 Chromatography: Liquid Chromatography is used to separate enantiomers. (S) – lactic acid. Computer illustration of a molecule of (S) – lactic acid (formula: $C_3H_6O_3$). Atoms are represented as cylinders and are colour-coded: carbon (yellow), hydrogen (white) and oxygen (red). Four different groups are joined to the central carbon atom here, a property known as chirality. The groups are given priorities based on their atomic number, and the molecule is viewed along the line of the bond to the lowest priority group. The order of the other groups decreasing priorities determines whether the isomer is classified as S (anti-clockwise, as here) or R (clockwise). (With permission from Prof. K. Seddon / Science Photo Library).

Colour Plate 33

Plate 33 Crystallization: Geocrystallization Crossed polarizer photomicrographs of (A) a glassy basalt, (B) a gabbro, (C) an andesite, (D) a diorite, (E) a rhyolite and (F) a granite. Each of these photographs was taken at the same magnification (horizontal field is 10mm across). The bulk composition of the magma forming the basalt and gabbro are broadly similar, as is the bulk composition for the andesite and diorite and the rhyolite and granite. The clearly observable differences in texture result from differences in crystal growth and nucleation rates. (A) Basalt showing large crystals (phenocrysts) of plagioclase feldspar (grey), Ca-rich pyroxene (purple, at centre) and olivine (yellow, top left) in a finer grained groundmass of these minerals. (B) Gabbro showing crystals of Ca-rich pyroxene (red-orange) enclosing plagioclase (grey-white with multiple twinning) and olivine (blue, green and red grains right of centre). (C) Andesite showing phenocrysts of plagioclase (grey-white with multiple twinning) and pyroxene (yellow-orange-red) set in a fine-grained glassy ground mass. (D) Diorite showing a rock comprised of plagioclase feldspar (grey-white multiply twinned crystals), pyroxene, amphibole (green) and interstitial quartz (yellow-grey). Note how the amphibole crystals form a jacket or coating on the pyroxene (centre). (E) Rhyolite showing perlitic cracking in glassy ground mass and phenocrysts of quartz and plagioclase (twinned). Note the corroded and resorbed grain boundaries of the phenocrysts. (F) Granite showing interlocking crystals of plagioclase (twinned), alkali feldspar (turbid, dusty appearance), quartz (clear) and biotite (speckly orange).

Colour Plate 35

Plate 35 Crystallization: Geocrystallization Mineral layering in the Rum Igneous Intrusion, NW Scotland. This photograph shows spectacular centimeter-scale mineral layering in Unit 14 of the Eastern Layered Series of the Rum Layered Igneous Intrusion. The Rum Intrusion forms one of a number of layered intrusions, including Skaergaard in East Greenland and The Cullins, on Skye, NW Scotland, which are part of the North Atlantic Tertiary Igneous Province. Now exhumed by the combined effects of erosion and uplift, these intrusions mark the site of crystallizing magma chambers 60 million years ago, during the early rifting stages of the North Atlantic Ocean. The near horizontal layers were formed by sequential precipitation of crystals of different composition (principally plagioclase, pyroxene, olivine and spinel) on the floor of a magma chamber. The darker layers are rich in the minerals olivine and pyroxene, the lighter layers richer in plagioclase. Mimicking sedimentary rocks where the principal hydraulic agent of sorting is a water column, in layered intrusions magma was the hydraulic agent and dense minerals, like spinel and olivine, settled more rapidly than plagioclase, leading to units which are graded from spinel and olivine-rich bases to plagioclase-rich tops.

Colour Plate 36

Plate 36 Crystallization: Melt Crystallization Sulphur deposits. View of yellow sulphur deposits around vents on the crater floor of the Mutnovsky volcano on the Kamchatka peninsula, Russia. These deposits are formed when hot sulphurous gases from the volcano condense and solidify when they meet the cooler air and rocks. The main gases involved are gaseous sulphur itself and hydrogen sulphide, which is oxidised by the air to sulphur and water. (Reproduced with permission from Science Photo Library.)

Colour Plate 37

Plate 37 Distillation: Freeze-Drying Isolator, Class 100, for filling, transportation and loading of vials into the freeze-drying plant. Decontamination of the isolator and the equipment therein is accomplished by vaporized hydrogen peroxide (VHP). The VHP 100® generator can be seen in the centre in front of the isolator. (Courtesy of Steris GmbH, Hürth, Germany.)

Colour Plate 38

Plate 38 Distillation: Historical Development Oil refinery. Oil refinery with towers and chimneys. In an oil refinery, crude oil is heated and passed through catalytic cracking towers to break up the heavy crude oil hydrocarbon molecules into lighter fragments. The resulting components, from heavy industrial oils and tars through to light fuels (like petrol and kerosene) and gas, are separated out. The components, called fractions, may then be processed. Photograph of the refinery at Milford Haven, Wales. (Reproduced with permission from Science Photo Library.)

Colour Plate 39

Colour Plate 40

Plate 40 Electrophoresis: Deoxyribonucleic Acid, Theory of Techniques for Separation DNA chip. Gloved hand holding a device for rapidly analysing samples of DNA (Deoxyribonucleic Acid) at the scene of a crime. The device (the “DNA chip”) is made of clear plastic. Narrow channels have been etched on the plastic by techniques similar to those used to make electronic microchips. Samples containing fragments of DNA are put in the channels. The fragments move apart when an electric current is applied (electrophoresis), allowing the DNA’s composition to be analysed. This device is suitable for genetic linkage studies and clinical diagnostics as well as forensic investigation. It was developed at the Massachusetts Institute of Technology (MIT), USA. (Reproduced with permission from Science Photo Library.)

Colour Plate 41

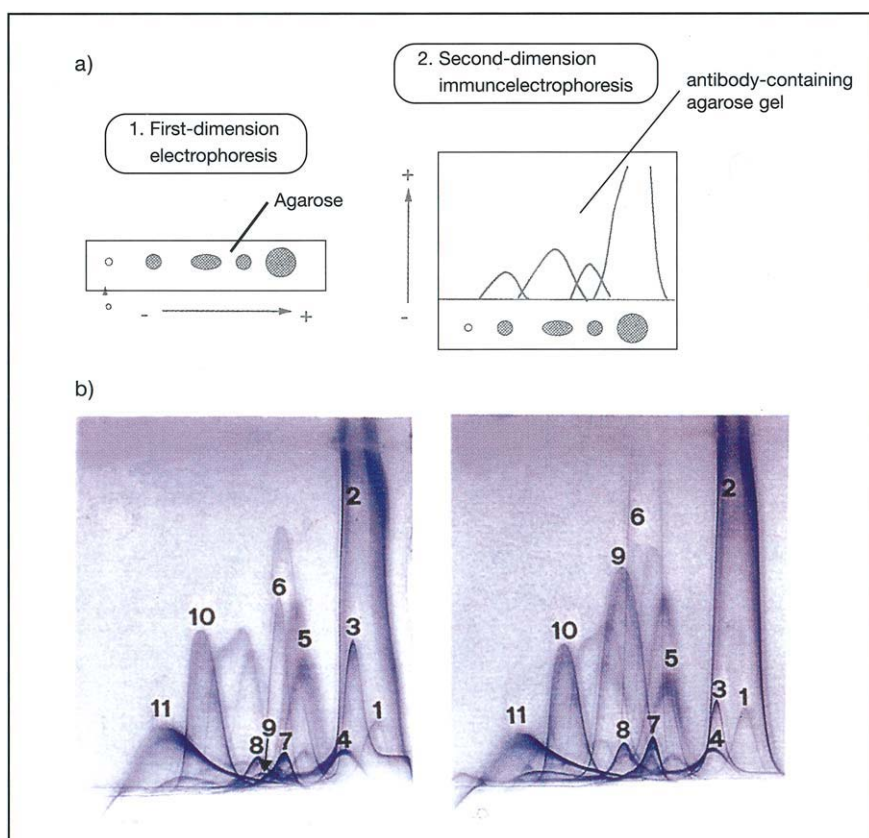

Plate 41 Electrophoresis: Immunelectrophoresis (A) Schematic illustration of crossed IE. 1, Agarose electrophoresis of the sample (O = origin, corresponding to the well where the sample is applied); 2, a longitudinal strip of the first-dimensional gel is transferred into a second-dimension gel containing a polyvalent antiserum. The second-dimension IE is performed perpendicularly to the first-dimension run. (B) Example of use of the crossed IE technique. The blood serum from the same pig is analysed (left) before and (right) 48h after turpentine injection. The changes in the protein concentrations, induced by inflammation, can easily be studied by analysing the area (or height) of the different-numbered peaks. (Reproduced with permission from Science Photo Library.)

Colour Plate 42

Plate 42 Electrophoresis: Gel Electrophoresis The inset shows the separation of human head hair proteins using 12 % sodium dodecyl sulfate-polyacrylamide gel electrophoresis with the point of migration of standard proteins to the left under the heading kDa: lanes 1 -3 *S*-carboxymethylated proteins; lane 4 reduced non-*S*-carboxymethylated proteins; lane 1 ^{14}C Autoradiograph; lanes 2 and 4, silver stain; lane 3, Coomassie stain. The main body of the figure shows a densitometric profile of the separated lane 1 (autoradiograph ^{14}C -*S*-carboxymethylated, green). Lane 2 (silver stain, *S*-carboxymethylated, red); lane 4 (silver stain, non-*S*-carboxymethylated). Molecular weights were extrapolated from a plot of log MWt vs. relative migration of standard proteins.

Colour Plate 46

Plate 46 Mass Spectrometry Portrait of Francis Aston (1877-1945), British physicist and Nobel Laureate. After WW1, Aston helped Thomson in his studies of the deflection of ions in magnetic fields. He went on to improve Thomson's apparatus, designing it so as to make all atoms of a given mass fall on the same part of a photographic plate. Working with neon, he found that two lines were observed, indicating the presence of two isotopes. He repeated this with chlorine with similar results. The device, called the mass spectrometer, showed that most stable elements had isotopes. His work earned him the 1922 Nobel Prize for Chemistry, and introduced a powerful new analytical tool to science. (Reproduced with permission from Science Photo Library.)

Colour Plate 47

Plate 47 Membrane Separations: Dialysis in Medical Separations Kidney (haemodialysis) machine, used for the removal of waste materials from the bloodstream of a person whose kidneys function insufficiently. A stream of blood from an artery is circulated through the machine on one side of a semipermeable membrane, while a solution of comparable electrolytic concentration circulates on the other side. Water & waste products pass across the membrane but blood cells & proteins are too large to do so. Purified blood is returned to the body through a vein. Circulating blood is visible inside the plastic tubing. (Reproduced with permission from Science Photo Library.)

Colour Plate 48

Plate 48 Membrane Separations: Diffusion Dialysis Chemical dialysis. Glassware used for purifying solutions by separating them from *colloid* chemicals using dialysis. During dialysis an impure solution is placed in a semi-permeable membrane (spheres) which is immersed in a pure solvent. Some of the chemicals within the membrane may pass out into the solvent by diffusion. The chemicals that remain trapped within the membrane are called *colloids*. *Colloids* usually consist of large molecules & tiny particles, although their exact composition depends upon the nature of the membrane. Colour Plate 75

Plate 75 Deoxyribonucleic Acid Profiling Gene mapping. A scientist studies a series of DNA sequencing autoradiograms or “genetic fingerprints” through a magnifying glass. He is determining the sequence of base pairs (cytosine, guanine, adenine, thymine) that form the code for a section of DNA. A sample of DNA has been cut into fragments by an enzyme and marked with a radioactive tag for sequencing. The DNA fragments are then separated by electrophoresis in an agarose gel, moving different distances along the gel according to their size. The resulting banding pattern, as seen here, is visualized by applying a radiographic film to produce these autoradiograms. (Reproduced with permission from Geoff Tomkinson/Science Photo Library.)

Colour Plate 76

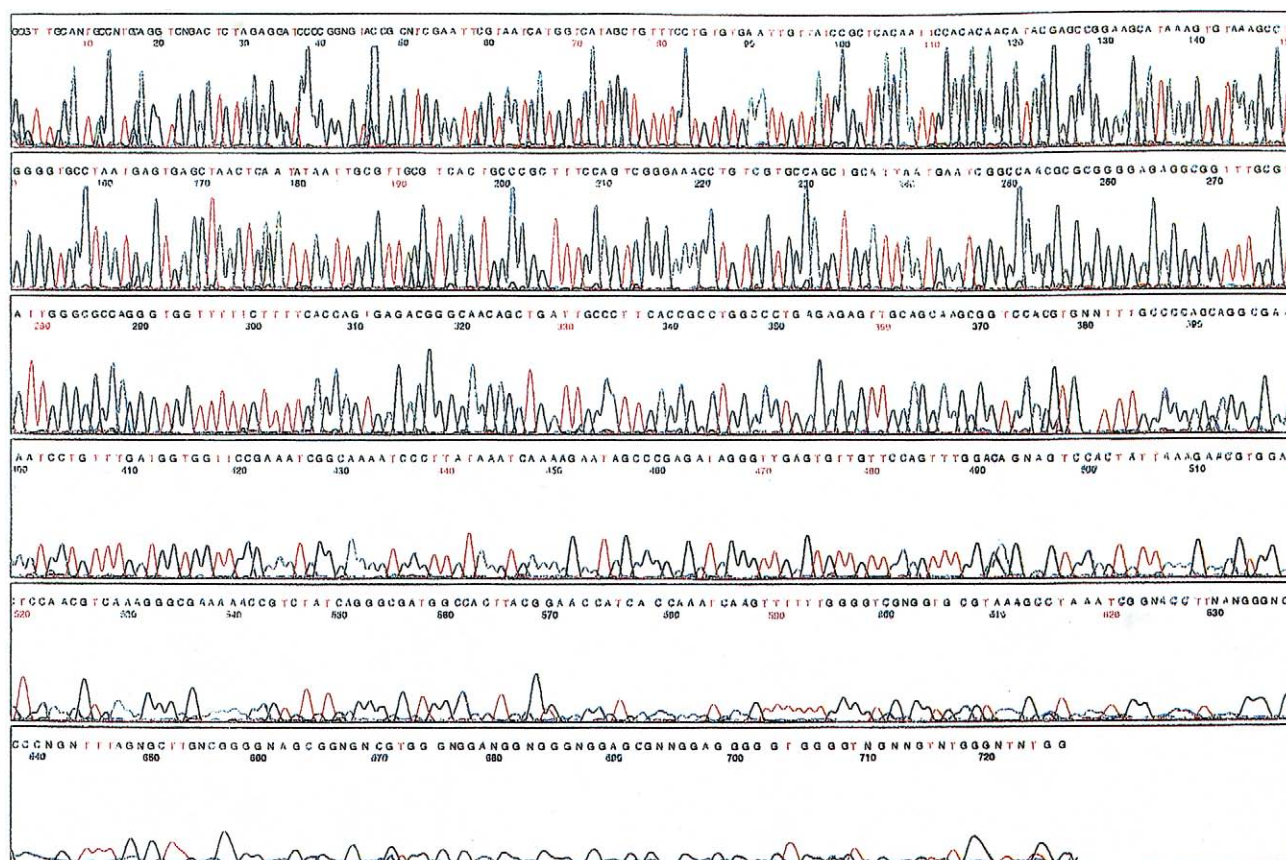

Plate 76 Deoxyribonucleic Acid Profiling: Capillary Electrophoresis Four-colour M13mp 18 sequencing separation at 42C. the separation of DNA sequencing fragments was performed in a 6.5% poly(dimethylacrylamide) (98kDa) solution (75cP) in 100 mmol L⁻¹ TAPS buffer (pH 8.0) containing 8 mol L⁻¹ urea. A 50mm i.d. fused silica capillary, 51cm long (40cm to the window) was used. DNA was electrokinetically injected for 20s at 60 V cm⁻¹, and the fragments were separated for 125 min at 160 V cm⁻¹. (Reproduced with permission from Madabhushi (1998), *Electrophoresis* 19: 224 - 230.)

Colour Plate 77

Plate 77 Dyes: Chromatography A scientist studying a selection of circular paper chromatograms of industrial dyes. Paper chromatography involves placing a small amount of the substance under investigation on a piece of filter paper, then slowly dripping a solvent into the centre of the paper. The solvent spreads out, over the paper by capillary action, carrying with it the components of the substance at differing rates. The distance travelled along the paper by each component during the time of the experiment is a measure of this characteristic transport rate and may be used to identify each component. (Reproduced with permission from Geoff Tompkinson/Science Photo Library.)

Colour Plate 78

Plate 78 Dyes: Thin-Layer (Planar) Chromatography Set of certified Congo red standards developed on a silica gel 60 HPTLC layer. Mobile phase: ethyl acetate-methanol-ammonia solution (0.88)-water (35 + 11 + 5 + 5 v/v). A minor impurity is visible at R_f value 0.07. The two dye substances alongside these are a dye that was claimed to be Congo red.

Colour Plate 79

Plate 79 Dyes: Thin-Layer (Planar) Chromatography Separation of brilliant cresyl blue on silica gel 60 HPTLC plate. Mobile phase ethyl acetate-methanol-ammonia solution (0.88)-water (35 + 11 + 5 + 5 v/v), saturated tank. Six standards applied at increasing concentration (from 50 ng) on the right side of the plate. The six samples developed on the left, all of equal concentration, were claimed to be brilliant cresyl blue, but in fact were a mixture of toluidine blue and Nile sulfate.

Colour Plate 80

Plate 80 An Adult Moth The development of insects from eggs through the larval stages to adults is under endocrine control. One of the groups of developmental hormones which control this process are the ecdysteroids. These compounds can be isolated from insects by a variety of separation techniques and chromatographic methods are used widely for their analysis. (Reproduced with permission from Sinclair Stammers/Science Photo Library.)

Colour Plate 81

Plate 81 Essential Oils A field of lavender, *Lavandula spica*. The name comes from the Latin for wash (lavare), referring to the plant's use in toilet preparations. It flowers between midsummer and early autumn, and it is harvested just before the flowers are fully open. It is a favourite plant of bees. Lavender has antitussive and antispasmodic properties. The essential oil obtained from the flowers is an excellent antiseptic and insecticide, and is reputed to neutralise a viper's venom. Photographed in Provence, France. (Reproduced with permission from Science Photo Library.)

Colour Plate 82

Plate 82 Essential Oils: Distillation Lavender oil is evaporated by steam in the still, condensed, and collected in a Florentine Flask. Jersey. (Reproduced with permission from Eye Ubiquitous.)

Colour Plate 83

Plate 83 Explosives Ammonium nitrate burning. An explosion of flames leaps out of a dish containing burning ammonium nitrate (NH_4NO_3). Ammonium nitrate is used in the manufacture of explosives and fertilisers. It was first used as an explosive by Alfred Nobel, founder of the Nobel Prize, who used it in his dynamite mixtures in 1875. Separations, particularly chromatographic, are important for the characterization of explosives, particularly in forensic contexts. (Reproduced with permission from Science Photo Library.)

Colour Plate 84

Plate 84 Fats Phospholipid bilayer. Molecular graphic of the phospholipid bilayer that forms the membrane around all living cells. There are many chromatographic methods for the separation and characterisation of lipids. The cell membrane is made of phospholipid molecules, each of which has a hydrophilic (soluble in water) and hydrophobic (insoluble in water) end. The hydrophobic part of the phospholipid is a fatty acid chain, shown here in blue. The molecules line up in two sheets, with the fatty acid chains forming a hydrophobic layer in the middle. The hydrophilic surface on both sides of the membrane, shown here in yellow and white, is the point of contact for molecules leaving or entering the cell. (Reproduced with permission from National Institutes of Health/Science Photo Library.)

Colour Plate 85

Plate 85 Herbicides: Gas Chromatography Scientist spraying part of an unripe grain field during a herbicide experiment. Residues of herbicides will persist in the plant or in the soil for a variable time, depending on their physiochemical properties and on the environmental conditions. Analysis of herbicide residues in these matrices is important, not only from the point of view of the efficacy of the application, but also to know the distribution and persistence of these compounds in food and the environment. Colour Plate 102

Plate 102 Isotope Separations: Gas Centrifugation Nuclear explosion. Aerial view of the nuclear explosion, code-named Seminole, at Enewetak Atoll in the Pacific Ocean on 6 June 1956. This atomic bomb was detonated at ground level and had the same explosive force of 13.7 thousand tonnes (kilotonnes) of TNT. It was detonated as part of Operation Redwing, an American programme, which tested systems for atomic bombs. (Reproduced with permission from Science Photo Library.)

Colour Plate 103

Plate 103 Lipids Computer graphic of part of a cholesterol molecule. Pink spheres represent carbon atoms, yellow spheres represent hydrogen and the lines represent the bonds between them. Cholesterol is an important constituent of cells, playing a crucial role in the synthesis of hormones and bile salts. It also helps to transport fats in the bloodstream to tissues throughout the body. (Reproduced with permission from US Department of Energy/Science Photo Library.)

Colour Plate 104

Plate 104 Marine Toxins: Chromatography Shuttle photograph of a phytoplankton, or algal bloom (a colouring of water arising from a high concentration of plankton) in a northwest Coral Sea off the Queensland Coast, Australia. Plankton drift more or less passively with the water flow, hence orbital photographs of plankton colonies can provide information on the prevailing currents. Here, the leading edge of a probable concentration of plankton is seen as a light irregular line and sheen in the sea at top right. Reports from ships in this area refer to floating mats of algae up to 2 metres thick. The discolouration of the water in and around the bay is due to the sediment load present in the rivers feeding into it. (Reproduced with permission from NASA/Science Photo Library.)

Colour Plate 105

Plate 105 Natural Products: Thin-Layer (Planar) Chromatography Thin Layer Chromatogram (TLC) of an extract of thylakoid membranes from the leaf of annual meadow grass *Poa annua*. TLC plastic sheets are coated with a 60 F254 silica gel that measures 0.2 millimetres thick. The extract was placed just above the solvent level at the bottom of the lane used to separate the sample. The picture shows the components of the extract separated according to their relative migration distance in the separation system. Six bands are seen; top (orange) is carotene; 2 (green) pheophytin; 3 (green) chlorophyll A; 4 (green) chlorophyll B; 5 (yellow) & 6 (mere trace) are carotenoids. The line across the top of the image is the solvent front. (Reproduced with permission from Science Photo Library.)

Colour Plate 106

Plate 106 Natural Products: Thin-Layer (Planar) Chromatography Taxol. Computer graphic of a molecule of taxol, an anti-cancer drug. The atoms and their bonds are colour-coded: carbon (C, dark blue); hydrogen (H, white); oxygen (O, red); nitrogen (N, light blue). Taxol has a chemical formula $C_{47}H_{51}NO_{14}$. It is found in the bark of the Pacific Yew tree, *Taxus brevifolia*, and can also be artificially synthesised. Taxol is particularly effective against advanced breast cancer and ovarian cancer. The drug works by inhibiting the protein *tubulin* to form microtubules, important structures involved in cell division (mitosis). The presence of taxol stabilises the microtubules, disrupting mitosis in the rapidly dividing cancer cells. (Reproduced with permission from Science Photo Library.)

Colour Plate 107

Plate 107 Neurotoxins: Chromatography Prairie rattlesnake's mouth. View of the open mouth and fangs of the northern Pacific prairie rattlesnake (*Crotalus viridis oreganus*). This is a subspecies of the prairie rattlesnake that lives in the north-western parts of North America. The fangs are seen enclosed by a membrane at the tip of the snake's upper jaw. These snakes feed mainly on small rodents, which they kill by injecting venom with these fangs. The prairie rattlesnake is widely distributed throughout western North America, with many subspecies existing. Their venom is dangerous and potentially fatal to humans. (Reproduced with permission from Science Photo Library.)

Colour Plate 108

Solvent II

Plate 112 Pharmaceutical: Crystallization Habit of a steroid crystallized from two different solvents.

Colour Plate 113

Plate 113 Pharmaceuticals: Crystallization Shape of particles obtained via spray drying. The left micrograph shows well-separated spherical particles typically obtained. Note the indentations on one side. The right micrograph shows felted needles that are in addition interwoven. Both products are fully crystalline.

Colour Plate 114

Plate 114 Pigments Lycopene. Computer graphic of lycopene, the red carotenoid pigment of tomatoes, rose hips and many other berries, and flowers of the pot marigold, *Calendula officinalis*. This hydrocarbon molecule contains two types of atoms: carbon (C, blue) and hydrogen (H, white). It has the chemical formula $C_{40}H_{56}$ (With permission from Science Photo Library.)

Colour Plate 115

Plate 115 Prostaglandins Aspirin. Computer graphic of a molecule of aspirin or acetylsalicylic acid, a pain killing (analgesic), anti-inflammatory drug used to treat fever, injuries, arthritis and heart disease. The lines represent the bonds between atoms, which are shown as colour-coded spheres: carbon is green, oxygen is red and hydrogen is white. Aspirin works by blocking the action of the *cyclooxygenase* enzymes, which produce hormone-like *prostaglandin* fatty acids. Some of these *prostaglandins* sensitise nerve endings and dilate blood vessels after an injury. Large doses of aspirin over long periods can lead to stomach and intestinal ulcers. (With permission from Science Photo Library.)

Colour Plate 116

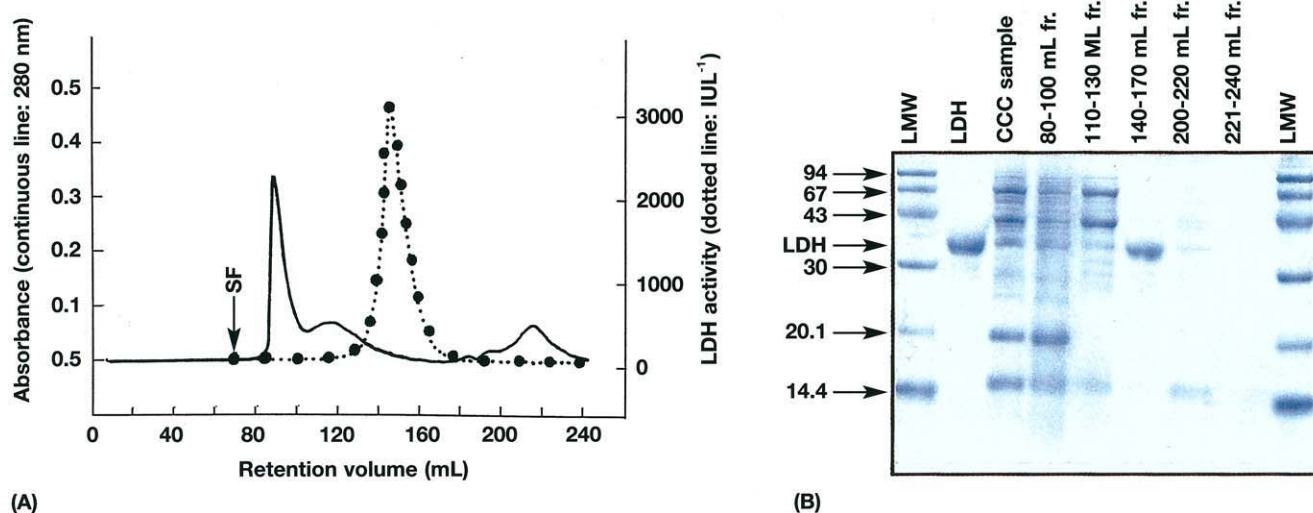

Plate 116 Proteins: High Speed Countercurrent Chromatography (A) Countercurrent chromatography of bovine heart homogenate and (B) SDS-PAGE profile of the fractions. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil, $\beta = 0.50-0.60$, 165 ml capacity; sample is a mixture of 3 ml bovine heart crude extract, 3 ml solvent system (1.5 ml each phase); solvent system consists of 16% (w/w) PEG 1000 12.5 % (w/w) potassium phosphate (pH 7.3); mobile phase is the lower phase; flow rate 2.0 ml min⁻¹; revolution: 500 rpm; SF, solvent front. LMW, low molecular weight protein markers.

Colour Plate 117

Plate 117 Sodium Chloride: Crystallization Polarised light micrograph of crystals of salt (sodium chloride). Salt crystals are built up from a cubic lattice of sodium and chlorine ions. In the absence of impurities an exact cubic crystal is formed. In practice the basic cube is often disrupted by dislocations giving rise to crystals with a variety of shapes, although they retain the underlying cubic symmetry. Magnification: x50 at 3mm size. (With permission from Science Photo Library.)

Colour Plate 118

Plate 118 Sugar Derivatives Dextrose. Polarised light micrograph of dextrose (glucose) sugar crystals. Magnification: x5 at 33mm size. (With permission from Science Photo Library.)

Colour Plate 119

Plate 119 Sulfur Compounds Garlic cloves and bulbs. View of several cloves and bulbs of garlic (*Allium sativum*). Garlic is a herb that is extensively used in cooking for its strong, distinctive taste. As well as its culinary uses, it is also a remarkable medicinal herb. It has powerful antibiotic properties when the juice is applied to wounds. It can also be used as an insect repellent. In common with other members of the onion family, it can help to reduce blood cholesterol levels and hypertension (high blood pressure). Oil of garlic is available in capsules for those who desire beneficial properties but dislike the taste. (With permission from Science Photo Library.)

Colour Plate 120

Plate 120 Thin-Layer Chromatography-Vibration Spectroscopy AFM photograph of a silver-coated HPTLC silica gel KG60 plate (post-overlayer SERS activation). NanoScope III; tapping mode.

Colour Plate 121

Plate 121 Thin-Layer Chromatography-Vibratlon Spectroscopy AFM (tapping mode) surface plot of a silver colloidal SERRS activated silica gel plate (KG60, Merck). A selected $X = Y = 500$ nm spot area of a $1\mu\text{l}$ of 10^{-10} M rhodamine 6G spotted on the plate. The silver hydrosol marker has a diameter of between 10 and 60 nm.

Colour Plate 122

Plate 122 Tobacco Volatiles Cigarette testing. Cigarettes being tested for the nicotine and tar content of their smoke during either medical research or as part of quality control in the tobacco industry. The cigarettes are being held vertically and having air sucked through them into the tubes in which their butts (brown) have been placed. The air will be analysed for its tar and nicotine content. Nicotine acts as a stimulant on the central nervous system and is the chemical that causes cigarette addiction. The tar is one of the numerous toxic by-products released by the burning of the cigarette. (With permission from Science Photo Library.)

Colour Plate 123

Plate 123 Triglycerides Olive harvesting. Orchard of olive trees *Olea europaea*, with nets laid around each tree to catch falling olives. Although this is a traditional way of harvesting olives, once the fruit is picked it is graded mechanically by size for pressing. Small olives have a higher oil content. The principal product of the cultivation of the tree is olive oil. *Olea europaea* has evergreen leaves and oval fruit coloured green, then black. This small tree is distributed around the Mediterranean region. Photographed in Apulia, Italy. (With permission from Science Photo Library.)

Colour Plate 124

Plate 124 Veterinary Drugs The demands for specificity, reliability, speed and turnover in residue analysis of veterinary drugs are continuously increasing. (With permission from Eye Ubiquitous.)

Colour Plate 125

Plate 125 Water Treatment Waste water treatment. Clarifying tanks used in the last stage of treating industrial waste water. In these tanks, water is passed through filters made of activated charcoal. Activated charcoal can be used to remove solid particles as well as soluble organic chemicals such as pesticides. (With permission from Science Photo Library.)

Colour Plate 126

Plate 126 Water Treatment Waste water treatment. View of waste water entering a pool at water treatment plant. The water is undergoing a preliminary flotation separation process. Detergent foam (lower centre) floats on the surface of the water. This allows the waste water to be drained off and treated separately. Photographed in England. (With permission from Science Photo Library.)

Colour Plate 127

Plate 127 Whisky: Distillation Whisky distillery, Glenfiddich. In general, during distillation of completely miscible liquids, the component with the higher boiling point moves towards the bottom of the still while the component with the lower boiling point moves towards the top. In whisky production, water boils at a higher temperature while ethyl alcohol boils at a lower temperature. As a result, the grain residue is naturally carried to the bottom of the still along with the water. (With permission from Spectrum Colour Library.)

Colour Plate 128

Plate 128 Wine View of grapevines, *Vitis vinifera*, in a wine vineyard. The grapevines are growing in ordered rows for ease of harvesting. The type of wine varies according to the soil, climate, variety of grape and the particular winemaking technique. Photographed at the Kunde Estate Winery, Sonoma County, California, USA. (With permission from Science Photo Library.)
